A single amino acid Gly-tag enables metal-free protein purification†

Landa Purushottam,^{‡a} Unnikrishnan V. B.,^{‡a} Dattatraya Gautam Rawale,^a Mansi Gujrati,^b Surya Dev Mishra,^{ab} Sajeev T. K.,^b Neelesh C. Reddy,^a Srinivasa Rao Adusumalli,^a Ram Kumar Mishra^b and Vishal Rai^{id*}^a

Analytically pure proteins are indispensable for diverse applications, including therapeutics. Here, we report a methodology where a single amino acid, glycine, enables metal-free protein purification. This robust platform is enabled by a Gly-tag resin for site-specific capture, enrichment, and release through chemically triggered C–C bond dissociation by resonance-assisted electron density polarization.

Introduction

Living systems are intricate, and a broad set of proteins drive their complex machinery. Elucidating the biological role of these individual proteins requires investigation of their physical, chemical, and structural properties. In turn, it necessitates the production of a pure functional protein of interest (POI). Classic natural sources took a back seat with time,¹ while recombinant protein expression caters to the growing academic and industrial demands.² The latter approach requires the isolation of the POI from the cell extract. The fishing out of a specific protein among thousand others with similar features is highly demanding. It needs a methodology to synchronize diverse aspects of chemical reactivity and selectivity. Besides, the restriction to operate under mild physiological conditions amplifies the complexity.

The initial efforts involved the development of affinity tags that can show unique capture and release attributes. In this perspective, immobilized metal-affinity chromatography is one of the most prominent techniques.³ Here, a sequence of His residues (His tag) installed in a protein provides preferential binding to a metal complex (x - z plane, Fig. 1). However, the non-specific binding to other residues in the proteins and leaching of metals are unavoidable. The quest for metal-free techniques and specific non-covalent interactions led to the development of peptide and protein-based fusion tags that operate under mild conditions (x - y plane, Fig. 1). The specificity in these cases requires a large recognition motif, either as a part of the protein or as the capture ligand on a resin.^{4,5}

Nevertheless, the loss of the protein is unavoidable due to the participation of multiple dynamic interactions that provide a gradient of binding energy. In contrast, the covalent immobilization of the POI at a specific site through a well-defined bond could offer a discrete switch ON mechanism for its capture. In this perspective, recent advances in the field of site-selective protein bioconjugation are encouraging.^{6–17} However, a chemical technology for the release of the POI under physiological conditions poses the next monumental challenge. This has been the prime reason behind the lack of methods for covalent affinity chromatography (y - z plane, Fig. 1). The problem is addressed indirectly by coding an additional enzyme-cleavable fragment, as in the case of HaloTag.¹⁸ Here, a protein with the tag can be installed on resin and allows

‡ These authors contributed equally to this work.

stringent washing with minimal loss of the POI. Although, the tag serves as a necessary evil due to its size (~34 kDa), making its removal an essential step. TEV protease releases the POI leaving behind the HaloTag on the resin. Consequently, the resin cannot be recycled, and the separation of the protease from the POI requires an additional step.

This necessitates a method that can enable covalent affinity chromatography under mild conditions with a small tag ($x-y-z$, Fig. 1), ideally a single residue. This technological demand requires a methodology that can offer residue specificity and result in the single-site labeling of a protein in a complex mixture. Subsequently, it would need the translation of chemistry to the solid phase for covalent immobilization of the POI without compromising its selectivity. Finally, the development of an on-demand chemically triggered release of the POI under mild conditions would be critical for a successful metal-free protein purification technology.

Protein bioconjugation mostly relies on carbon-heteroatom bond formation.^{19,20} Such bonds are easy to maneuver as they avoid the high energy required for C-C bond formation or dissociation. Recently, we developed the residue-specific labeling of N-Gly in proteins (Fig. 2a).¹¹ It is noteworthy that the installation of a single Gly residue at the N-terminus of a protein during its expression is convenient.²¹ Here, we demonstrate that a single residue (Gly) at the N-terminus can facilitate site-specific immobilization of proteins with a stable C-C bond (step 1, aldol reaction, Fig. 2b). Importantly, we have successfully developed a methodology that enables chemically triggered release of the protein (step 2, retro-aldol reaction,

Fig. 2b). The orthogonal nature of the C-C bond formation, its dissociation, and efficiency under the mild operating conditions are remarkable. The functionalized Gly-tag purification resin developed for this technology is robust and regenerated for multiple uses. The combination of all the attributes enables a single Gly residue at the N-terminus of a protein (Gly-tag) for metal-free covalent affinity purification.

Results and discussion

Immobilization of the Gly-capture reagent on NHS Sepharose resin

At first, we synthesized the aldehyde with proximal hydrogen bond acceptors (**2a**, Fig. 3a) in four steps (Fig. S1 and S2†). We tethered this Gly-tag capture element to a PEG diamine and placed a nucleophilic amine functionality at the other end of the reagent (**2a**). The PEG linker regulates the surface availability of the reagent upon its immobilization.²² On the other hand, the amine functionality provides the nucleophilic handle to conjugate it with the electrophilic NHS ester functionalized resin (**4**). Next, we quantified the extent of immobilization of the Gly-capture reagent on the Sepharose resin by UV analysis (Fig. 3a). Initially, we monitored the concentration of NHS at 260 nm (λ_{max}). However, the reagent **2a** also contributes to the absorption at this wavelength. To avoid ambiguity, we selected the additional absorbance of the unbound reagent **2a** at 308 nm to monitor the extent of immobilization. Initially, we derived the standard calibration curve from **2a** at different concentrations of the reagent (Fig. 3b and S4†). Subsequently, we determined the molar extinction coefficient of the reagent ($6.518 \text{ M}^{-1} \text{ cm}^{-1}$) **2a**. With this information in hand, we were able to monitor the synthesis of the Gly-tag purification resin through the concentration of the unbound reagent.

Fig. 2 (a) Selective labeling of N-terminus Gly containing proteins.¹¹ (b) Hypothesis for Gly-tag enabled protein purification includes successful realization of protein capture (step 1) through engineered Sepharose resin **5** and its release (step 2) under mild operating conditions.

Fig. 3 (a) Synthesis of the Gly-tag purification resin. (b) Determination of the molar extinction coefficient of the reagent **2a**. (c) Estimation of unbound reagent **2a** by UV absorption after reaction with resin **4** (2.3 μmol).

Interestingly, just two equivalent of reagent **2a** (4.6 μmol with 2.3 μmol of resin **4**) was enough to result in 20 $\mu\text{mol ml}^{-1}$ loading. It is consistent with the expected loading capacity of commercially available NHS ester functionalized Sepharose resin **4** (16–23 $\mu\text{mol ml}^{-1}$) (Fig. 3c). The UV spectrum of the washed fraction allowed the estimation of the adsorbed reagent. Also, the higher stoichiometry of the reagent did not result in noticeable improvement of the loading (Fig. S4†).

Immobilization of N-terminus Gly proteins on modified resin

Next, we selected a therapeutic protein (insulin, **1a**) for examining the method for immobilization of N-terminus Gly containing proteins on Gly-tag purification resin (**5a**). Insulin (**1a**) has two chains where N²-NH₂ of chain B is Phe, and that of chain A is a Gly residue. We anticipated that the N-terminus Gly would form a stable aminoalcohol product **8a** with the resin **5a**, thereby immobilizing the insulin (Fig. 4a). An aldol reaction would result in the C–C bond formation between an enolate and aldehyde. We analyzed the insulin-capture using the absorbance of unbound insulin (at 280 nm). When 20 nmol of insulin was vortexed with 400 μl of the resin **5a**, we observed the complete disappearance of the insulin absorption peak for the supernatant, indicating excellent binding (>90% efficiency, Fig. 4b). Subsequently, the resin was thoroughly washed to remove any adsorbed protein. ESI-MS and UV-Vis analysis confirmed that no protein remained in the solution. Also, we were able to rinse the resin with several portions of buffer without releasing the bound protein. The robust immobilization through C–C bond formation facilitates ordered single-site immobilization and opens a gateway for developing other biochemical tools and biomaterials.^{23–26} Alongside, we selected myoglobin (**1b**, N-Gly) and SUMO1 (**1d**, N-Gly) to re-validate the

efficiency of the Gly-tag purification resin (Fig. S5 and S8†). Interestingly, the method translated well for their immobilization. In the control experiment, RNase A (**1c**, N-terminus Lys) did not result in any reaction with **5a** (Fig. 4c). This confirmed the selectivity of the Gly-tag purification resin towards the Gly at the N-terminus of the protein.

Screening of additives for C–C bond dissociation in the aminoalcohol

At this stage, we were poised to tackle the most critical challenge. The final element of the technology required a methodology for aminoalcohol C–C bond dissociation under physiological conditions. Initially, we thought that base-mediated deprotonation of hydroxyl could trigger a retro-aldol reaction. To examine the theory, we employed various organic bases (**11a–11g**, Fig. 5a) and mixed them with the labeled insulin (**9**). However, all these additives were unable to initiate the release. With a stronger organic base, TMG (**11h**, Fig. 5a), we were able to observe a retro-aldol reaction (20% conversion, see Fig. S7†). However, it was too slow indicating that direct employment of a base would not serve the purpose. We reasoned that lowering the pK_a of hydroxyl might be critical for performing the reaction under mild conditions. We hypothesized that transforming the amine (**12**, Fig. 5b) to imine (**13**) combined with an appropriate resonance-assisted electron density (RED) polarization might address the requirement. We postulated that pyridoxal 5'-phosphate (PLP, **11i**) could provide the extended conjugation and activate the aminoalcohol **12** (Fig. 5b). Hence, the formation of imine (**13**) could enable the abstraction of the hydroxyl proton. The

feasibility would depend on the additional pull effect provided by the PLP (**11i**). To test this conjecture, we decided to monitor the reaction of the aminoalcohol product with PLP (**11i**) in the solution phase. To generate the aminoalcohol product (**12**), we modified the N-terminus of native insulin with a bis-aldehyde (**S8**) (Fig. S6†).¹¹ We were delighted to note that PLP (**11i**, 50 equiv., 0.1 M NaHCO₃ buffer, pH 7.8) promoted the retro-aldol reaction with 98% conversion within 2 h (Fig. 5a and Table S1†; for myoglobin and SUMO1, see Fig. S8†). Importantly, we do not observe the potential side-reaction of N-aldehyde introduction under our reaction conditions.²⁷ Further, we revalidated the absence of the aldehyde by mixing the reaction mixture with benzyloxyamine. The remarkable chemoselectivity of our release methodology is noteworthy. Also, it is absolutely essential for the success of Gly-tag technology.

Purification of the protein of interest from a mixture of proteins and cell lysate

Subsequently, we investigated the retro-aldol reaction with immobilized proteins (Fig. 6a). The PLP (1 μmol in 0.1 M NaHCO₃ buffer, pH 7.8) mediated C–C bond dissociation results in 86–98% release of insulin and myoglobin within 2 h (Fig. 6b and S8†). We removed the PLP **11i** by centrifugal spin concentration and isolated the pure insulin (**1a**) with a conserved structure (for CD, see Fig. S9†). Similarly, immobilized myoglobin (**8b**) also yielded pure protein **1b** upon PLP assisted

release (Fig. 6b and S8†). To investigate the efficiency of the methodology in selective capture and release of the N-Gly protein, we selected a mixture of proteins having diverse residues at the N-terminus. The protein mixture comprised insulin **1a**, aprotinin **1e**, ubiquitin **1f**, cytochrome C **1g**, lysozyme C **1h**, β-lactoglobulin **1i**, and chymotrypsinogen A **1j** (Fig. 6c). To our delight, we were able to purify insulin **1a** from the mixture of proteins while conserving the efficiency (Fig. 6e and S10†). Also, the protocol allows excellent recovery and recyclability (five times) of the Gly-tag purification resin without substantial loss of activity (Fig. 6d; for recyclability with cell lysate, see Fig. S10c†). Finally, we checked if we could purify a protein of interest from the cell lysate (Fig. 6c). We overexpressed the protein modifier, SUMO1 protein (**1d**), in the *E. coli* BL21 (DE3) strain, with the recognition sequence for preScission protease. The post-proteolytic digestion resulted in a Gly residue at the N-terminus. Remarkably, the protein is captured and released selectively to yield pure SUMO1 (**1d**, Fig. 6f, 50% recovery yield, and 30-fold enrichment by SDS-PAGE). The protocol also extends conveniently to the purification of insulin from the cell lysate (Fig. S10c†). Moreover, the activity of purified SUMO1 and insulin remains unperturbed (Fig. S11 and S12†).

Conclusions

In summary, we developed a chemical technology that establishes a single amino acid (N-Gly) as the covalent affinity tag. We

built the initial platform based on our residue-specific N-Gly labeling strategy. It enabled us to develop a Gly-capture reagent that delivered high efficiency even in the solid phase. The resulting functionalized Gly-tag purification resin facilitated selective capture of the protein of interest (POI) while leaving the other proteins in solution. Importantly, we were successful in developing a methodology for C–C bond dissociation under mild conditions. This on-demand reversibility proved critical for the operation of the overall technology and enabled the release of the POI. Besides, the recovery and recycling of the Gly-tag purification resin allowed us to reduce the cost of operation. The technology facilitates the separation and isolation of N-Gly tagged proteins from a mixture of proteins and cell lysates.

Experimental

Procedure for N-Gly protein purification

N-Hydroxy succinimidyl Sepharose beads 4 (400 μ l, resin loading: 23 μ mol ml^{−1}) were taken in a 5 ml fritted polypropylene chromatography column with end tip closures. Sodium bicarbonate buffer (0.1 M, pH 7.8, 3 \times 1 ml) was used to wash the beads and they were re-suspended (sodium bicarbonate buffer, 360 μ l, 0.1 M, pH 7.8). To this solution, 2a (13.8 μ M) in DMSO (40 μ l) from a freshly prepared stock solution was added and vortexed at 25 °C. The progress of the immobilization of the reagent on Sepharose resin was monitored using the UV-absorbance of the supernatant. Subsequently, the supernatant was removed and the beads were washed with aqueous buffer (0.1 M NaHCO₃/0.5 M NaCl pH 8.0, 3 \times 1 ml; 0.1 M acetate/0.5 M NaCl pH 4.0, 3 \times 1 ml) and H₂O (3 \times 1 ml) to remove the adsorbed reagent from the resin (stored at 4 °C). The Sepharose beads 5a were washed with the aqueous buffer (0.1 M NaHCO₃/0.5 M NaCl pH 8.0, 3 \times 1 ml) and re-suspended (aqueous buffer, 375 μ l, 0.1 M NaHCO₃/0.5 M NaCl pH 8.0). To this solution, the native protein (20 nmol) dissolved in sodium bicarbonate buffer (25 μ l, 0.1 M, pH 7.8) was added and vortexed at 25 °C. Binding was ensured using UV-Vis analysis. The beads were washed thoroughly with aqueous buffer (0.1 M NaHCO₃/0.5 M NaCl pH 8.0, 3 \times 1 ml), 1 N KCl (3 \times 1 ml) and H₂O (3 \times 1 ml) to remove any non-specifically bound protein from the resin. This was confirmed by analyzing the final wash fraction using LC-MS. For eluting out the bound protein, pyridoxal 5'-phosphate 11i (50 equiv.) in 0.1 M NaHCO₃ buffer (pH 7.8) was added to the resin and vortexed for 2 h at 25 °C. Hydroxyl amine was added before a final round of spin concentration. The eluted protein was analysed by using ESI-MS and SDS-PAGE.

Labeling of the protein in the solution phase

In a 1.5 ml Eppendorf tube, protein 1a (3 nmol) was mixed with sodium bicarbonate buffer (120 μ l, 0.1 M, pH 7.8). To this solution, S8 (1500 nmol) in DMSO (30 μ l) from a freshly prepared stock solution was added and vortexed at 25 °C. The overall concentration of the protein and S8 was 20 μ M and 10 mM respectively. After 24–48 h, the reaction mixture was

diluted with acetonitrile : water (10 : 90, 3000 μ l). Unreacted 2-(2-formylphenoxy)acetic acid and salts were removed by using an Amicon® Ultra-0.5 ml 3 kDa or 10 kDa MWCO centrifugal filter spin concentrator. The protein mixture was further washed with Millipore Grade I water (5 \times 0.4 ml). The sample was analyzed by ESI-MS. The aqueous sample was concentrated by lyophilization before subjecting it to digestion, peptide mapping, and sequencing by MS-MS.

Author contributions
