Elastomer-immobilized tunable colloidal photonic crystal films with high optical qualities and high maximum strain†

Hiroyuki Tajima, Ami Amano and Toshimitsu Kanai *

High-quality elastomer-immobilized colloidal crystal films with low particle volume fractions can be prepared using hydrogel-immobilized single-crystalline colloidal crystal films processed by shear flow. The solvent-free elastomer film demonstrated a full-colour change from red to blue with high uniformity over a cm² scale, achieved by varying the mole fraction of monomers in the hydrogel. Owing to the low particle volume fraction, the elastomer film exhibited a colour change from red to blue upon stretching, and the maximum strain reached 120%. The film provided reversible and repeatable colour changes during extension without residual strain. The prepared films have the potential to be used in simple strain sensors to express invisible strains through colour change.

Introduction

Periodic arrays of monodisperse colloidal particles, that is, colloidal crystals, embedded in a soft polymer, act as tunable photonic crystals.^{1–21} Because the volume of the soft polymer can be altered by external stimuli, the lattice constant of the colloidal crystals varies, and hence, their optical properties can be tuned on demand. For example, colloidal crystals immobilized in a hydrogel can change the optical stop-band wavelength or Bragg reflection colour through changes in the gel volume corresponding to environmental changes such as temperature,^{1,2} pH,^{3,4} ionic strength,^{5–8} and solvent.^{9,10} These properties are also expected to be applicable in simple sensors and indicators that detect changes in environmental conditions and indicate those through changes in the reflection colour. One of the most intriguing applications of such tunable photonic crystals is a strain sensor.^{11,12} For example, when these sensors are attached to a constructed wall, such as a building, bridge, or tunnel, small amounts of strain which are normally invisible can be readily detected on sight through colour change without requiring expensive tools and prior training. However, hydrogels generally have low mechanical strength, especially against extension, and evaporation of swelling solvent into the ambient atmosphere,⁸ which hinders their practical use.

Solvent-free colloidal crystals immobilized in an elastomer are a possible solution.^{13–18} They can be prepared by filling interstices of opal-type close-packed colloidal crystals with elastomers.^{13–16} Elastomer-immobilized colloidal crystals without solvent are stable in the ambient atmosphere and have sufficient mechanical strength to allow stretching. However, maximum strain has been limited to approximately 50% because the extension caused a significant rearrangement of particles in the opal-based colloidal crystals with a very high particle volume fraction of more than 0.4.^{13–16} Recently, elastomer-immobilized colloidal crystals with a low particle volume fraction have been developed. They were prepared by polymerization of elastomer precursor solutions containing charge-stabilized colloidal crystals.^{17,18} Owing to the electro-repulsive interaction among particles, particles were separated from each other as they crystalized in the elastomer precursor solutions and were immobilized in the elastomer by polymerization at a low particle volume fraction (*e.g.* 0.234¹⁷ and 0.33¹⁸). Because the large interparticle separation suppressed particle rearrangement during the extension, the maximum strain was improved to approximately 70%.^{17,18} If elastomer-immobilized colloidal crystals with even lower particle volume fractions are prepared, they may exhibit a higher maximum strain.²² However, this preparation is a challenge because strong electrorepulsive interactions are not generally generated in elastomer precursor solutions. In addition, although optical qualities, especially the uniformity of Bragg reflection colour over a large area, are essential for practical applications, those of colloidal crystals prepared using the common methods are not high because they provide polycrystalline structures.

We have found that charge-stabilized colloidal crystals in water^{23–25} with a lower particle volume fraction of approximately 0.1 can be single-crystallized over a large area of a cm² scale by a shear flow effect in a flat capillary cell.^{26–29} Moreover, loosely packed colloidal crystals can be immobilized in a hydrogel film without deterioration of the high crystalline qualities by the subsequent photopolymerization of gelation reagents previously dissolved in water.^{30,31} If water contained in the hydrogel film is replaced by an elastomer precursor solution that is then polymerized intact, elastomer-immobilized colloidal crystal films with high optical qualities and a lower particle volume fraction can be obtained. However, in general, when a hydrogel film is immersed in an elastomer precursor solution for replacement, the film shrinks significantly, destroying the crystal structure.

In this report, we demonstrate that elastomer-immobilized colloidal crystal films with a very low particle volume fraction exhibiting high optical qualities and high maximum strain can be achieved using gel-immobilized single-crystalline colloidal crystal films by the proper combination of the hydrogel and the elastomer. We used hydrogels composed of comonomers of *N*-isopropylacrylamide (NIPAM) and *N*-methylolacrylamide (NMAM) with different NIPAM mole fractions to adjust the affinity between the hydrogel and the elastomer precursor solution. Hydrophilic 4-hydroxybutyl acrylate (HBA) was used as the elastomer precursor. We examined the dependence of the particle volume fraction and Bragg reflection wavelength of elastomer-immobilized colloidal crystal films on the NIPAM mole fraction. In addition, the tunable properties of the elastomer-immobilized colloidal crystal films at extension were examined.

Results and discussion

Preparation of elastomer-immobilized colloidal crystal films

The method for preparing gel-immobilized single-crystalline colloidal crystal films has already been reported,^{30,31} and a brief description is given below. An aqueous suspension of monodisperse polystyrene particles (Thermo Scientific, particle diameter: 160 nm) was deionised by adding a mixed-bed ion-exchange resin (Bio-Rad, AG501-X8(D)) and stirring gently. Gelation reagent (NIPAM and NMAM as monomers, *N,N'*-methylenebisacrylamide (BIS) as a cross-linker, and 2,2'-azobis[2-methyl-*N*-(2-hydroxyethyl)propionamide] (VA) as a photo-initiator) and ultrapure water were added to the suspension to achieve monomer, cross-linker, photo-initiator, and particle concentrations of 800 mM, 40 mM, 0.35 mM, and approximately 10.7 vol%, respectively. The colloidal suspension with different NIPAM mole fractions x ($x = [\text{NIPAM}]/([\text{NIPAM}] + [\text{NMAM}])$) was shear-flowed into a flat capillary cell (channel height: 0.1 mm; width: 9 mm; length: 70 mm) to convert into a single-domain crystal (Fig. 1a).^{26–29} Ultraviolet (UV) light was irradiated uniformly from both sides of the cell to photopolymerize the gelation reagent (Fig. 1b).^{30,31} The obtained gel film containing single-crystalline colloidal crystals was removed from the cell and cut into circular fragments with a diameter

Fig. 1 Schematic representation of preparation process for elastomer-immobilized colloidal crystal films.

of 4.5 mm (Fig. 1c). A rectangular fragment with a length of 20 mm and width of 9 mm was cut from the gel film with $x = 0.50$. The films were immersed in an elastomer precursor solution of HBA with 1 wt% of photo-initiator (BASF Japan Ltd, DAROCUR 1173) for approximately 24 h to replace the water contained in the gel film with the precursor solution. The films were placed between two glass slides using cover glasses as spacers, and the UV light was irradiated to photopolymerize the HBA (Fig. 1d).

Fig. 2 shows photographs and reflection spectra of the colloidal crystal film with $x = 0.50$ at each preparation step. Before gelation, the colloidal crystal exhibited a uniform texture with a bright red colour over the entire sample area, which was achieved by the shear flow effect. The reflection spectrum showed a strong peak at 679 nm, which was derived from the Bragg reflection from the (111) lattice planes of the face-centred cubic (FCC) structure parallel to the sample surface.^{26–29} After gelation, uniform colour and an excellent spectral profile were preserved. When the gel-immobilized colloidal crystal film was cut into the circular fragments and immersed in the elastomer

Fig. 2 Photographs and reflection spectra of the colloidal crystal film with $x = 0.50$ at each preparation step.

precursor solution, the uniform colour and the peak shape were retained. After the photopolymerization of the precursor, the film shrank, and the particle volume fraction increased to 0.155. As a result, the reflection peak was blue-shifted to 654 nm. However, excellent optical properties such as the uniform reflection colour and the strong reflection peak were almost fully retained.

The change in the Bragg wavelength after the conversion from the gel film to the elastomer film can be quantitatively explained by the contraction of the FCC(111) lattice spacing and the change in the refractive index of the colloidal crystals using Bragg's law at normal incidence:

$$\lambda_{hkl} = 2n_c d_{hkl}, \quad (1)$$

where λ_{hkl} is the Bragg wavelength, n_c is the refractive index of the colloidal crystals, and d_{hkl} is the lattice spacing of the (hkl) planes. The volume-weighted average of the refractive indices of the components of colloidal crystals is a good approximation of n_c :^{8,32}

$$n_c = n_p \phi_p + n_m(1 - \phi_p), \quad (2)$$

where n_p and n_m are the refractive indices of the polystyrene particles ($n_p = 1.59$) and the matrix of the elastomer film, respectively, and ϕ_p is the volume fraction of polystyrene particles in the elastomer film. Because the matrix consists of poly(*N*-isopropylacrylamide) (PNIPAM), poly(*N*-methylolacrylamide) (PNMAM), and poly(4-hydroxybutyl acrylate) (PHBA), n_m can be approximated as $n_m = (n_{\text{PNIPAM}}\phi_{\text{PNIPAM}} + n_{\text{PNMAM}}\phi_{\text{PNMAM}} + n_{\text{PHBA}}(1 - \phi_p - \phi_{\text{PNIPAM}} - \phi_{\text{PNMAM}}))/(1 - \phi_p)$, where n_{PNIPAM} , n_{PNMAM} , and n_{PHBA} are the refractive indices of the PNIPAM ($n_{\text{PNIPAM}} = 1.45$), PNMAM ($n_{\text{PNMAM}} = 1.41$), and PHBA ($n_{\text{PHBA}} = 1.49$), respectively, and ϕ_{PNIPAM} and ϕ_{PNMAM} are the volume fractions of the PNIPAM and PNMAM in the elastomer film, respectively. The d_{111} value is determined using ϕ_p and the diameter d of colloidal particles:

$$d_{111} = \left(\frac{2\pi}{9\sqrt{3}\phi_p} \right)^{\frac{1}{3}} d \quad (3)$$

Because the volume change of the film is isotropic in three dimensions during solvent replacement and photopolymerization, the volume ratio α of the elastomer film to the gel film is calculated using the measured diameters of the elastomer film D and the gel film D' as follows:

$$\alpha = \left(\frac{D}{D'} \right)^3 \quad (4)$$

Assuming that the volumes of the colloidal particles, PNIPAM, and PNMAM are constant during the preparation process, the volume fractions of the particles ϕ_p^i , PNIPAM ϕ_{PNIPAM}^i , and PNMAM ϕ_{PNMAM}^i in the elastomer film can be estimated using α as

$$\phi_p^i = \frac{\phi_p}{\alpha}, \quad (5)$$

$$\phi_{\text{PNIPAM}}^i = \frac{\phi_{\text{PNIPAM}}}{\alpha}, \quad (6)$$

$$\phi_{\text{PNMAM}}^i = \frac{\phi_{\text{PNMAM}}}{\alpha}, \quad (7)$$

where ϕ_p^i , ϕ_{PNIPAM}^i , and ϕ_{PNMAM}^i are the volume fractions of the colloidal particles, PNIPAM, and PNMAM in the gel film swollen in water, respectively. These values can be calculated from the Bragg wavelength and the masses of the gelation reagent added to the water.^{2,8} By substituting ϕ_p^i , ϕ_{PNIPAM}^i , ϕ_{PNMAM}^i , D , and D' into eqn (4)–(7); ϕ_p^i , ϕ_{PNIPAM}^i , and ϕ_{PNMAM}^i were determined. The values for n_c and d_{111} of the elastomer film were calculated by substituting ϕ_p^i , ϕ_{PNIPAM}^i , and ϕ_{PNMAM}^i into eqn (2) and (3). Thus, the Bragg wavelength of the elastomer film was estimated to be 657 nm by substituting n_c and d_{111} into eqn (1). This value is in good agreement with the measured Bragg wavelength of 654 nm.

We found that the affinity of the gel film to HBA was greatly changed by x . Thus, the particle volume fraction and the Bragg reflection wavelength of the resultant elastomer-immobilized colloidal crystal film could be greatly altered by x (Fig. 3 and Fig. S1, ESI†). When x decreased, the gel film shrank significantly in the precursor solution. High uniformity was preserved, and the resultant elastomer film exhibited a full-colour change: red ($x = 0.50$), yellow ($x = 0.40$), green ($x = 0.35$), light blue ($x = 0.30$), and blue ($x = 0.20$) (Fig. 3). The particle volume fraction at $x = 0$ was calculated to be 0.503. In contrast, when x was increased, the gel film swelled well in the precursor solution. In particular, the swelling volume of the gel film with $x = 1.0$, in the precursor solution was larger than that of the gel film in water. As a result, surprisingly, the particle volume fraction of the elastomer film with $x = 1.0$ was 0.111. This signifies that the solvent-free elastomer film can realize a lower particle volume fraction than the gel-immobilized colloidal crystal film swollen in water (*i.e.* 0.114). The observed Bragg wavelengths of the elastomer films with various x values are plotted as filled circles in Fig. 3. At x values exceeding 0.80, the Bragg wavelength attained a near-IR range. These plots are in good agreement with the plots calculated using eqn (1)–(7), which are shown as open diamonds.

Fig. 3 Plots of the Bragg wavelength and photographs of the elastomer-immobilized colloidal crystal films as a function of x (●: experimentally measured Bragg wavelength, ◇: calculated Bragg wavelength).

Tunable properties of the elastomer-immobilized colloidal crystal film at extension

The elastomer-immobilized colloidal crystal film showed a full-colour change at extension and exhibited a maximum strain of 120%, which is, to date, the highest value reported for elastomer-immobilized colloidal crystals. As shown in Fig. 4a, when the film with $x = 0.50$ was stretched, various reflection colours (red, orange, yellow, green, and blue) were observed, corresponding to the strain ($\varepsilon = ((L^e - L^i)/L^i) \times 100$, L^e : film length at extension, and L^i : film length without extension), while preserving uniformity over a cm^2 scale. In the reflection spectrum, the Bragg peak was gradually blue-shifted from 660 to 488 nm as the strain was increased to 120% (Fig. 4b and c). The intensity of the peak decreased upon stretching. This is explained by the decrease in the refractive index contrast between a slice containing the (111) plane at the middle and an intermediate slice.¹⁸ Fig. 4d shows the sensitivity, that is, the amount of change in the Bragg wavelength responding to strain, estimated by the slope of the graph of the Bragg wavelength as a function of strain (Fig. 4c). The sensitivity decreased with increasing strain and became a very low value of less than 1 nm/% at a strain of 120%.

The blue shift of the Bragg peak is caused by the reduction of the lattice spacing perpendicular to the thickness direction of the film; hence, the Bragg wavelength during extension can be estimated from the film thickness. The lattice spacing d_{hkl}^e at extension is given by the film thickness t^e at extension, film thickness t^i without extension, and lattice spacing d_{111}^i without extension as follows:

$$d_{hkl}^e = \frac{t^e}{t^i} d_{111}^i \quad (8)$$

Because the particle volume is constant during the extension, the particle volume fraction ϕ_p^e at extension is given by the volume of the elastomer film V^i without extension and the volume of the elastomer film V^e at extension, which are calculated by the area and the thickness, as follows:

$$\phi_p^e = \frac{V^i}{V^e} \phi_p^i \quad (9)$$

Assuming that n_m does not change by stretching, n_m is the refractive index of the matrix without extension. n_e under strain is determined by substituting n_m and ϕ_p^e into eqn (2). Thus, the Bragg wavelengths at various strains were estimated by substituting d_{hkl}^e and n_e into eqn (1), and plotted as open diamonds in Fig. 4c. These plots were in good agreement with the observed Bragg wavelengths.

Fig. 4e shows the time-course change in the Bragg wavelength of the elastomer film after releasing the extension with a maximum strain of 120%. At 10 s after release, the Bragg wavelength showed a 5% difference in the initial wavelength and became almost identical to the value after 1 min. Fig. 4f shows the thickness ratios of t^e to t^i for the elastomer film with $x = 0.50$, and for the elastomer film without particles. The two films showed the same dependence of thickness on strain. In addition, the Poisson's ratios of both films had the same value

Fig. 4 (a) Photographs of elastomer-immobilized colloidal crystal film with $x = 0.50$ at various strains. The length of the scale bars is 5.0 mm. (b) Reflection spectra of the film at various strains. (c) Bragg wavelength of the film as a function of strain ($\bullet$: experimentally measured Bragg wavelength, $\diamond$: calculated Bragg wavelength). (d) Sensitivity of the film estimated from c. of 0.39, which was estimated by the gradient of the plots of $-\ln(t^e/t^i)$ vs. $\ln(L^e/L^i)$ up to a maximum strain of 120% (Fig. S2, ESI†).³³ These data indicate that the colloidal crystals in the

Fig. 5 (a) Spectral change of the elastomer-immobilized colloidal crystal film with $x = 0.50$ by repeating the stretch and release. (b) Photographs and Bragg wavelength of the film by repeating the stretch and release 3 times. The length of the scale bars is 5.0 mm.

elastomer film do not affect the deformation of the elastomer even at a maximum strain of 120% because of the very low particle volume fraction. In addition, the relatively low Poisson's ratio of the elastomer film contributed to the high maximum strain.

Fig. 5a shows the spectral change of the elastomer film by repeating the stretch and release between strains of 10% and 35%. The Bragg peak blue-shifted from 637 to 586 nm during the stretch and returned to the initial wavelength after the release, preserving the excellent spectral profile (Fig. 5a). The uniform reflection colour was also intact after the repetitions (Fig. 5b). The film was fully reversible, and the colour change was repeatable with elastic deformation, which was achieved by the large interparticle separation in the colloidal crystals with a very low particle volume fraction. The variations in the Bragg wavelength and the intensity of the reflection did not exceed a few percent after repeating the extension with the maximum

strain of 120% and the release 100 times, and no damage was observed on the film.

Conclusions

In summary, we succeeded in preparing elastomer-immobilized colloidal crystal films with high optical qualities and a low particle volume fraction, realizing the benefits of hydrogel-immobilized single-crystalline colloidal crystal films processed by shear flow. By the proper combination of the copolymer hydrogel consisting of NIPAM and NMAM monomers and the hydrophilic HBA elastomer precursor, the shrinkage of the gel film during solvent replacement was suppressed; thus, the high-quality colloidal crystals could be immobilized in solvent-free elastomer films intact. Furthermore, we found that the gel film composed of the NIPAM monomer swelled to a greater degree in the HBA than in water, and therefore, the particle volume fraction in the resultant elastomer film could be greatly altered between 0.111 and 0.503 by varying the mole fraction of monomers. This leads to elastomer films exhibiting a full-colour change from red to blue with high uniformity over a cm^2 scale. Owing to the very low particle volume fraction, the elastomer film exhibited a full-colour change from red to blue when stretched, without rearrangement of particles, and the maximum strain reached 120%. This is the highest value reported to date for elastomer-immobilized colloidal crystals. In addition, because the particles remain untouched during stretching, no residual strain remains. Thus, the film exhibited reversible and repeatable colour changes during extension. The films have the potential to be used in simple strain sensors to detect invisible strains through colour change.

Experimental

Preparation of gel-immobilized colloidal crystal films

An ion-exchange resin (Bio-Rad, AG501-X8(D)) was added to an aqueous suspension of monodisperse polystyrene particles (Thermo Scientific, particle diameter: 160 nm), and the mixture was gently stirred for deionization. The formed charge-stabilized colloidal crystals were centrifuged to increase the particle concentration. Gelation reagents (NIPAM (FUJIFILM Wako Pure Chemical Corp.) and NMAM (FUJIFILM Wako Pure Chemical Corp.) as monomers, BIS (FUJIFILM Wako Pure Chemical Corp.) as a cross-linker, and VA (FUJIFILM Wako Pure Chemical Corp.) as a photo-initiator) and ultrapure water (Millipore, Milli-Q system) were added to the colloidal crystals so that the concentrations of the monomers, cross-linker, photo-initiator, and particle were 800 mM, 40 mM, and 0.35 mM, and approximately 10.7 vol%, respectively. Colloidal crystals with different NIPAM mole fractions x ($x = [\text{NIPAM}] / ([\text{NIPAM}] + [\text{NMAM}])$) were prepared and bubbled with Ar gas for 5 min to remove dissolved O_2 and CO_2 . The colloidal crystals were shear-flowed into a flat capillary cell (channel height: 0.1 mm; width: 9 mm; length: 70 mm) to convert into a single-domain crystal. The obtained particle array of the single crystal was immobilized in the hydrogel network by UV light

irradiation using a UV light device (MORITEX SCHOTT, MBRL-CUV7530). Photographs of the samples before and after UV light irradiation were taken using a CCD camera (Sony, XCD-V60CR) through a macro zoom lens (Edmund Optics, MLH-10X), and the reflection spectra were measured using a multi-channel spectrometer (Soma Optics, Fastevet S-2630).

Preparation of elastomer-immobilized colloidal crystal films

The gel film containing single-crystalline colloidal crystals was removed from the cell and cut into circular fragments of 4.5 mm diameter. For the tensile testing, the gel film with $x = 0.50$ was cut into a rectangular fragment 20 mm long and 9 mm wide. The gel films were immersed in HBA (Tokyo Chemical Industry Co., Ltd) with 1 wt% of a photo-initiator (BASF Japan Ltd, DAROCUR 1173) for approximately 24 h to replace the water in the gel with the elastomer precursor solution. Slide glasses were coated with toluene (FUJIFILM Wako Pure Chemical Corp.) with 5 wt% of silicone oil (Shin-Etsu Chemical Co., Ltd, KF-96A-50CS) as a release reagent and heated at 350 °C for 1 h in an electric furnace (Tokyo Rikakikai Co., Ltd, TMF-4100). The gel films, swollen in the elastomer precursor solution, were placed between the two glass slides using cover glasses (thickness: approximately 0.15 mm) as spacers. The films were irradiated with UV light (MORITEX SCHOTT, MBRL-CUV7530), both above and below. Photographs of the films before and after UV light irradiation were taken using a CCD camera (Sony, XCD-V60CR) through a macro zoom lens (Edmund Optics, MLH-10X), and reflection spectra were measured using a multichannel spectrometer (Soma Optics, Fastevet S-2630).

Tensile testing of elastomer-immobilized colloidal crystal film

The film was pinched 5 mm from both edges and stretched at 1.0 mm intervals. At each step, photographs of the film were taken from above using a CCD camera (Sony, XCD-V60CR) through a macro zoom lens (Edmund Optics, MLH-10X). The side view of the film was observed using a CCD camera through a video lens (Edmund Optics, VIDEO LENS-VZM 600) to measure the film thickness. The reflection spectra of the stretched films were measured using a multichannel spectrometer (Soma Optics, Fastevet S-2630).
