With over millions of years of evolution, viruses can infect cells efficiently by utilizing their unique structures. Similarly, the drug delivery process is designed to imitate the viral infection stages for maximizing the therapeutic effect. From drug administration to therapeutic effect, nanocarriers must evade the host's immune system, break through multiple barriers, enter the cell, and release their payload by endosomal escape or nuclear targeting. Inspired by the virus infection process, a number of virus-like nanosystems have been designed and constructed for drug delivery. This review aims to present a comprehensive summary of the current understanding of the drug delivery process inspired by the viral infection stages. The most recent construction of virus-inspired nanosystems (VINs) for drug delivery is sorted, emphasizing their novelty and design principles, as well as highlighting the mechanism of these nanosystems for overcoming each biological barrier during drug delivery. A perspective on the VINs for therapeutic applications is provided in the end.

1. Introduction

Viruses are core–shell entities co-assembled from nucleic acids and proteins, with sizes ranging from 20–900 nm.[1] As a non-cellular life, a virus is inert outside, but it can replicate itself inside the host cell.[2] With over millions of years of evolution, viruses have been able to bypass the immune system's surveillance effectively.[3] By taking advantage of the amphoteric charges, they can prolong their blood circulation time to obtain enough time for cell infection.[4–6] Attachment is the first step of viral infection. The polyvalent ligand–receptor

Zhihuan Liao

Zhihuan Liao obtained his B.S. degree from the Guangdong Medical University in 2020. Subsequently, he joined the group of Prof. Shuaidong Huo at Xiamen University as a post-graduate student. His research interests include bioinspired and biofunctionalized nanomaterials for drug delivery.

Xing-Jie Liang

Xing-Jie Liang obtained his Ph.D. degree at the National Key Laboratory of Biomacromolecules, Institute of Biophysics, Chinese Academy of Sciences (CAS). He finished his post-doctorate under the guidance of Dr Michael M. Gottesman, a member of NAS and Deputy Director of NIH. Then, he worked as a research fellow at Surgical Neurology Branch, NINDS, NIH. Dr Liang is currently a principal investigator at the National Center for Nanoscience and Technology of China and a chair-professor at Xiamen University. His research interests are elucidating mechanisms to improve nanomedicinal drugability and developing novel strategies to increase therapeutic efficiency.

interactions or spiky surface morphology can transform the viral envelope proteins, allowing viruses to enter and penetrate the cell.[7] For some viruses, the replication step mainly takes place in the cell nucleus. The presence of nuclear localization signals (NLS) enables viruses to specifically target the nucleus, thus entering and releasing their genomes for replication.[8] In addition, the interaction between the viral surface with cellular components and their microenvironment is likewise conducive to the viral infection steps.[9] It is noteworthy that the coat protein and structural morphology of viruses play irreplaceable roles in crossing various physiological barriers and attaching to host cells during the whole infection process.

Inspired by the efficient viral infection process, various bioengineered vectors have been developed for cargo delivery in biomedical applications.[10,11] For example, adenoviral and lentiviral vectors with high transfection efficiency have been used to treat multiple diseases,[12] such as hemophilia,[13] cystic fibrosis,[14] tumors,[15] *etc*. However, the direct use of viruses as a conveyance still has many safety risks, including broad viral tropism, high immunogenicity, and pathogenicity, significantly limiting their further applications.[16–19] In recent decades, the prosperous development of nanotechnology has resulted in unprecedented strategies for biomedicine, especially for drug delivery.[20–22] A number of conventional nanocarriers have been developed for drug delivery, including polymeric nanoparticles (NPs),[23] solid lipid NPs,[24] inorganic NPs,[25] *etc*. Despite numerous efforts, limitations are still multifaceted. First, the carrier must effectively escape the clearance of immune systems, then cross the biological barriers and cell membrane while avoiding endosomal entrapment. Moreover, the nanocarrier requires excellent stability outside the cell, and must effectively target and release the payload inside the nucleus. To overcome these challenges, fortunately, virus-inspired nanosystems (VINs) have been constructed and shown unique superiority for drug delivery.[26–29] By simulating the original composition and topological structure of viruses, VINs with high biocompatibility have been successfully exploited. In general, VINs have editable physicochemical properties, and can flexibly cross the barriers and deal with the changes of the surrounding physiological environment for delivery.[30,31] In addition to delivering genes, VINs can also be used to deliver a range of therapeutic drugs.[32,33] Thanks to the large space of the hollow structure, encapsulation of therapeutics in VINs can improve their water solubility, loading efficiency, and biocompatibility.[34,35] Furthermore, the virus-like design of VINs can promote a better biological distribution and higher cellular uptake efficiency.[36,37] More importantly, the characteristic of easy surface functionalization of VINs might further push them to cross the boundary of clinical translation for disease treatment.[38]

In this review, we summarized the state of the art of strategy for constructing VINs for drug delivery, with an emphasis on their novelty and design principles. Meanwhile, the mechanism of these nanosystems for overcoming each biological barrier during drug delivery is highlighted, including prolonged blood half-life, endothelial barrier breaking, enhanced cellular uptake, endosomal escape and nuclear targeting (Fig. 1). Finally, the challenges and an outlook on the VINs for drug delivery are discussed.

2. Prolonged blood circulation

The blood half-life of drug vectors refers to their retention time in the bloodstream, which directly reflects the pharmacokinetic properties of the carriers. Generally, foreign nanocarriers tend to bind with proteins or biomolecules non-specifically in the blood, forming the so-called corona that promotes their clearance by the immune system. Remarkably, some viruses have the ability to evade the capture of the immune system, which inspires us to design similar structures for drug delivery.[39,40] This section describes virus-inspired strategies to prolong blood circulation by simulating the inherent viral traits.

The blood half-life of NPs is dependent on their shape, size, and surface charge.[41–43] Compared with spherical NPs, the velocity gradient of the fluid environment in the blood circulation leads to the uneven distribution of forces, which more likely affects the trajectory and drift of the rod-shaped NPs in the blood flow and promotes their adhesion to the target position.[44] Filoviruses, single-stranded RNA viruses, have a filamentous or branched polymorphic structure with a diameter of about 80 nm and a length of up to 1400 nm. Under the influence of fluid dynamics, filoviruses are stretched as they flow, thus prolonging their circulation time and enhancing the viral transport efficiency.[45] The available evidence has suggested that filiform is a more elaborate rod structure, and the retention effect of filamentous micelles in the circulation is better than that of spherical NPs.[46] Inspired by filoviruses, Geng *et al.* evaluated the anticancer effect of the flexible material containing paclitaxel by controlling the average

Shuaidong Huo

Shuaidong Huo obtained his Ph.D. degree from the National Center for Nanoscience and Technology of China in 2016 under the supervision of Prof. Xing-Jie Liang. After that, he worked as a post-doctoral researcher in Prof. Andreas Herrmann's team at the DWI-Leibniz Institute for Interactive Materials, Germany. In January 2020, he joined the School of Pharmaceutical Sciences, Xiamen University as a Professor. His research topic focuses on taking advantage of nanotechnology to understand the biological effect of nanomaterials on living systems and develop activity-regulatable drug delivery systems for disease treatment.

length of the material (Fig. 2A).[47] They compared the clearance time of PEG copolymer filamentous micelles and PEGylated "stealth" vesicles at the same dose. The result showed that the circulation time of the former was up to one week, while the latter was cleared quickly in two days. Similarly, researchers have developed a uniquely shaped artificial tobacco mosaic

virus (ATMV) to mimic the high aspect ratio structure advantage of TMV. ATMVs with elongated shapes are concealed in the blood until they reach the tumor site to induce tumor killing (Fig. 2B).[48] Distinctly, the shape effect of the virus further enhanced the advantages of PEG as a cloaking material and achieved the synergistic impact of prolonging the blood half-life, providing a more effective passive tumor accumulation.

In addition, adjusting the surface charge of the nanocarriers can reduce the formation of the protein corona, which is also beneficial for drug delivery.[4] A study of TMV showed that virus-inspired nanosystems (VINs) were six times less capable of binding to proteins than synthetic nanosystems.[49] The formation may be caused by the combination of positive and negative charges with hydrophobic and hydrophilic domains on the patching.[50] Similarly, a study demonstrated that nanosystems with the amphoteric charges were found to inhibit protein crown formation more effectively than the positively, negatively, or uncharged particles.[51] The reduced serum protein adsorption might result from the amphiphilic particles with less hydrophobic or electrostatic interaction domains. In another study, inspired by the process by which viruses effectively pass through epithelial tissues using electrical neutrality, VINs based on mesoporous silica nanoparticles (MSN–NH_2@COOH/CPP5) were designed to improve insulin absorption by simulating the electrical neutrality of the virus surface. Owning to VINs ability to overcome the epithelial cell barrier and increase their concentration in the blood, the bioavailability of the drug is further improved (Fig. 2C).[52]

In terms of the size effect, generally, NPs smaller than 10 nm in diameter can be cleared rapidly by the kidneys, while NPs larger than 200 nm have the risk of activating the complement system.[20] VINs with diameters in the range of 20–200 nm have been constructed for drug delivery,[53] and the optimization of 50 nm (Fig. 2D) solves the problem of insufficient blood circulation time to some extent.[54] In a word, nanosystems that mimic the viral membrane composition and physicochemical properties have significantly prolonged blood circulation time relative to conventional nanosystems.

3. Endothelial barrier breaking

It is well known that the low permeability of the vascular endothelium, especially the tight junctions, such as the blood–brain barrier (BBB), is another major obstacle for drug delivery.[55,56] To overcome this challenge, nanocarriers need to diffuse into the dense extracellular matrix at high interstitial pressures, or cross endothelial cells using receptor-mediated endocytosis and then be excreted to the other side.[6,57] In this section, taking the BBB as an example, the virus-inspired strategies to overcome the endothelial barriers are discussed.

The existence of the BBB makes it harder for drugs to cure brain diseases. At present, the strategies for treating brain diseases by penetrating the BBB mainly include invasive techniques,[58] receptor-mediated transport (RMT),[59] and adsorption-mediated transcytosis (AMT).[60] Although great efforts have been contributed for brain-targeting, there is an urgent need to develop more efficient carriers that can penetrate the BBB efficiently and safely. Inspired by the excellent ability of the rabies virus (RABV) to invade the central nervous system (CNS) by RMT,[61,62] a drug carrier composed of a brain-targeting peptide called RVG29 from RABV for delivering deferoxamine was reported (Fig. 3A).[63] Interestingly, the drug carriers can effectively repair the damage to dopaminergic neurons without affecting the normal function of other organs by significantly reducing oxidative stress levels of the brain. Similarly, the metal–organic framework-based nanosystems simulating the natural bullet-shaped structure and surface features of RABV were designed (Fig. 3B).[64] Compared with the simple imitation of RABV individual function, they benefit from a more comprehensive RABV imitation strategy, showing an apparent enhancement of BBB penetration and better treatment of brain tumors.[65] Besides, Neves *et al.* found that a peptide called PepH3 of the dengue virus type 2 capsid protein can be used for BBB penetration and the translocation mechanism is consistent with AMT (Fig. 3C).[66] Biological distribution data *in vivo* showed that the radio-labeled derivative peptides exhibited high brain permeability, and PepH3 reached the equilibrium distribution concentration of BBB within 24 hours. The study suggested that PepH3 is an excellent candidate for shuttling peptides into the brain. Undoubtedly, inspired by the viral infection process, a combination of the surface receptors and physicochemical characteristics of the virus provides the main idea to break endothelial barriers for intracerebral targeted drug delivery.

4. Enhanced cellular uptake

Viral infections mainly depend on the binding ability of viruses with the cell membranes.[67] In this process, the surface morphology and the presence of polyvalent ligands of viruses are critical to them for overcoming a series of membrane barriers.[8] This section focuses on the implications of enhanced cellular uptake of virus-inspired nanosystems (VINs) for improving drug delivery efficiency.

4.1. Polyvalent ligands

A virus infects a cell by the recognition and attachment with the cell membrane receptor.[68,69] The presence of capsid protein surface ligands is one of the main factors that determines the success of cell entry. Therefore, imitating the polyvalent ligand on the surface of the virus can greatly improve the cellular uptake efficiency of the drug carriers. It is widely studied that the HBV induces liver damage by recognizing the viral envelope protein with heparan sulfate proteoglycan on human liver cells.[70] Further study showed that large proteins, especially the N-terminal myristoylated pre-S1(2–47) domain, were the key factor promoting HBV cellular targeting and entry.[71] Inspired by HBV, a liposome that showed high specificity for human hepatocytes was synthesized by modifying the

HBV envelope L protein on nanocarriers.[72] The virus-inspired liposome modified with targeting peptides was used to deliver chemotherapeutic drugs to specifically target xenograft mice and achieve outstanding efficacy for inhibiting tumor growth. Similarly, by mimicking the envelope of the virus, a polyelectrolyte complex composed of chitosan-modified L-phe derivative copolymer and insulin fusion protein was designed.[73] The structure improved the absorption and bioavailability of oral insulin through the mucous layer and intestinal epithelial penetration.

In order to identify cells more accurately, Figueroa *et al.* constructed a nanocarrier composed of PEG polylactic acid (PEG–PLA), hydrophobic polylactic-co-glycolic acid (PLGA), and angiotensin I (Ang-I) by simulating the recognition mechanism of cells by the influenza A virus (Fig. 4A).[74] The binding process is divided into two stages. In the first stage, the binding of Ang-I and angiotensin-converting enzyme (ACE) produces the secondary ligand Ang-II. In the second stage, Ang-II can specifically bind to another cell membrane receptor.[7] The prepared nanocarriers cannot recognize the off-target cells that only carried the primary or secondary ligands, thus greatly improving the recognition accuracy of the target cells. After further optimization of the original VINs, the nanocarriers have a more accurate cell targeting ability and can recognize cells by three consecutive checks compared with nanocarriers lacking one or both receptors.[75] However, the extracellular enzyme ligands are required in this recognition process, which has certain limitations for cells lacking the corresponding enzymes. To overcome this barrier, adenovirus (AD)-mimetic VINs were developed for enhancing the specific recognition of cells.[76] In short, the Ang-II type-1 receptor (AT1r) blocker EXP3174 and the $\alpha_v\beta_3$ integrin agonist cRGDfK were attached to block-copolymers of varying lengths and then modified on the surface of NPs. When they entered the body, the VINs attached to the cell membrane through the specific binding of EXP3174 with AT1r on the cell membrane. Then the

binding of cRGDfK with $\alpha_v\beta_3$ initiated the clathrin-mediated endocytosis. These studies not only provide valuable strategies for increasing targeting ability and reducing the toxicity of nanocarriers, but also put forward new insights into the development of drug delivery systems.

4.2. Surface morphology

The cellular uptake efficiency of drug carriers can be increased by simulating the surface morphology (*e.g.*, rough surface and spike) of viruses, such as herpes simplex virus and HIV.[77–79] For example, the modification of polyethylenimine (PEI) on the surface of the NPs can increase their surface roughness. Compared with the smooth NPs, the rough NPs exhibited better-combining ability, which greatly improved the cellular uptake efficiency.[80] In another study, an organosilica nanosystem with a low Young's modulus (36 MPa) was constructed by imitating the rough surface of the virus.[81] Ultrasmall SiO_2 NPs were closely attached on the surface of larger mesoporous organic SiO_2 NPs to explore the impact of the surface roughness and softness on cell internalization and tumor infiltration. Surprisingly, the VINs showed an 18.49-fold increase in tumor penetration compared with the hard mesoporous organosilica nanospheres. Similarly, taking advantage of viral topology and carrier-free nanosystems, a nanosystem (PEI/DNA@DNPs) was constructed by loading hydrophobic doxorubicin onto electrostatically bound PEI/DNA (PD) polymer spheres.[82] These nanosystems can be used in chemotherapy and gene therapy. In addition, the spikes of the virus are also confirmed to have a significant influence on its membrane penetration. For example, a spike-like MSN with zinc ligands on its surface showed a high affinity for phosphate-rich cell membranes, and the enhanced membrane fusion was conducive to the cellular uptake of nanocarriers (Fig. 4B).[83] Therefore, the surface morphology of the virus is also worthy of reference for the design of drug delivery carriers.[84,85]

4.3. Pore-mediated membrane penetration

Some viruses, such as bacteriophages, adenoviruses (AD), *etc.*, can attach to the cell membrane through pore-mediated membrane penetration and deliver the genome directly to the host cell.[86,87] Inspired by this process, a stable gene delivery system γPGA/L4/DNA was designed and constructed using cationic polymer L4, DNA and polyacrylic acid (γPGA) (Fig. 4C).[88] In this complex structure, L4 with an octyl side chain can penetrate the phospholipid bilayer stably, while the strong electrostatic mutual repulsion between γPGA and DNA enables the gene to be directly delivered into the cytoplasm for transfection. The VINs avoided the interference of gene transfection

due to endocytosis and prevented DNA degradation from lysosomal phagocytosis. Nevertheless, it has been found that the transfection ability of the DNA–cationic polymer complex is highly concentration-dependent. At low concentrations, most of the complex particles will spontaneously disassemble and the rest could not cause the "proton sponge effect" of endosomes, which leads to a loss of transfection ability of VINs. To overcome this problem, Zhang *et al.* constructed VINs with tunable hydrophobicity by systematically studying the relationship between the hydrophobicity of cationic polymers and DNA transfection capacity (Fig. 4D).[89] In this study, γ-PGA was stabilized by the hydrophobic polymer through electrostatic interactions. When in contact with the cell membrane, it fell off to release DNA for dose-independent transfection. This result indicated that the VINs could infect cells independently even at low concentrations, similar to the concentration-dependent transfection of viruses.

5. Endosomal escape

Enveloped viruses release their cargo by fusing with the endosomal membrane.[90,91] Unlike enveloped viruses, non-enveloped viruses have two mechanisms by which they realize endosomal escape: the carpet-like mechanism resulting from membrane destruction and barrel-stave mechanism for the formation of transmembrane pores.[67,92,93] In this section, virus-mimetic endosomal escape strategies for cargo release are discussed.

5.1. Membrane fusion mediated endosomal escape

A number of experiments indicate that fusion proteins mediate the membrane fusion process.[94] The fusion proteins undergo conformational changes to insert in the endosome with a low pH microenvironment and subsequently fuse with the exposed hydrophobic residues into the lipid bilayer, resulting in cytoplasmic transport of the genome. Inspired by the encapsulated camouflage process that most enveloped viruses utilize the phospholipids of host cells, virus-inspired nanosystems (VINs) embedded with functional polypeptides have been reported.[95] In this study, the viral antigen gene was cloned into lentiviral vectors, then transfected into eukaryotic cells to express the viral antigen. Then the viral antigen was delivered to the cell surface to produce a mass of cell membrane vesicles. The results indicated that viral envelope glycoproteins could be added to the surface of liposomes to mimic the properties and conformational epitopes of natural viruses. Similarly, enlightened by the escape process of the influenza virus, a virus-like nucleic acid nanogel was constructed for glioblastoma treatment (Fig. 5A).[96] In this study, the influenza virus HA2 peptide in VINs was able to fuse with the lysosomal membrane to achieve endosomal escape of VINs. In addition, the pH-sensitive fusogenic peptide can also achieve a similar result apart from endosome membrane fusion by mimicking the entire envelope camouflage strategy of the virus. For example, Chol–GALA (a cholesterylated pH-sensitive fusogenic peptide) and PEG–GALA can be used for compound modifications to enhance endosomal escape.[97,98] To this end, Sasaki *et al.* designed a multifunctional envelope-type nanosystem Tf–MEND by encapsulating the concentrated plasmid DNA into envelope-like nanosystems containing PEG–Tf, Chol–GALA, and PEG–GALA, which can induce the interaction between liposomes and endosomes.[99] In the artificial viral nanosystems, the structure of GALA changes with the decrease of the pH value of the environment, resulting in increased hydrophobicity and thus enhanced interaction with the lipid membrane. Besides, Chol–GALA and PEG–GALA can also interact with the capsule and penetrate the endosomal membrane depending on topological control, thereby synergically destabilizing the membrane structure and inducing membrane fusion.

5.2. Membrane destruction mediated endosomal escape

During the process of adenovirus (AD) escaping from the endosome, its capsid components will undergo conformational transformations with the changes of the cellular signal, causing the exposure of membrane–lytic protein VI to promote the escape from the endosome. Inspired by this, based on AD capsid pentamyl protein, a pH-sensitive bucket structure of pentameric units could be constructed artificially.[100] In this study, the pentameric units disrupted the endosomal membrane by protonation and triggered its decomposition, thus facilitating the delivery of intracellular cargos. Similarly, a polymeric NP (ADMAP) mimicking the virus capsid protein was constructed for delivering antitumor drugs (Fig. 5B).[101] Poly (lauryl methacrylate-*co*-methacrylic acid), a polymer molecule with endosomal membrane destruction function was modified on the surface of ADMAP NPs by nanoprecipitation. As pH decreases, ADMAP NPs can escape the endosome and release the drug through pH-dependent membrane destruction. In another study, inspired by the effective escape process of the dengue virus using a pH-sensitive peptide, Mable *et al.* synthesized dengue virus simulated NPs using biomimetic technology for triple-negative breast cancer treatment (Fig. 5C).[102] The strong pH responsiveness of VINs in an acidic endosomal environment resulted in endosomal rupture and cargo release into the cytoplasm. In addition, the protonation of amino groups forced the endosome to break under high osmotic pressure, allowing the payload to escape from the endosome due to the proton sponge effect.[103]

As an amino-rich polycation material, PEI has been known as the gold standard for proton sponge-based delivery of nucleic acids. Recently, a copolymer drug carrier using branched PEI for efficient siRNA delivery has been designed.[104] In response to the acidic microenvironment in the cell, PEI cleavage resulted in endosomal membrane destruction. Meanwhile, the practical promotion of endosomal escape by disassembly of NPs was achieved. This approach provides a new potential approach to address the bottleneck of intracellular siRNA delivery. Similarly, poly(amidoamine) (PAMAM) also has a high acid-response ability to trigger endosomal escape. For example, Weiss *et al.* designed multifunc-

tional MSNs modified with a PAMAM dendritic surface structure.[105] Thanks to the intrinsic expansion of PAMAM during the acidification of the endosome, MSNs can eventually lead to endosomal membrane rupture and drug release through a disulfide bond mediated mechanism. These studies demonstrated that simulating the viral endosomal escape process could be helpful for boosting drug delivery.

Nevertheless, some polymers cannot destroy the endosomal membrane, and an alternative strategy is to consider adding membrane destroying polypeptides into the delivery system. For example, Cheng *et al.* analyzed the assembly behavior of the synthesized virus–inspired polymer (VIPER) for endosome release at pH 7.4 and pH 5.7.[106] A cationic compound mellitoxin that has robust membrane-destroying ability was used in this study.[107,108] The result indicated that acidic environments triggered the hydrophilic transition of poly(2-diisopropylaminoethyl methacrylate)-*co*-poly(pyridyl disulfide ethyl methacrylate) blocks which exposed melittin, thereby disrupting the endosomal membrane. Thus, endosomal escape in this study is facilitated by the enhancement of the polycation block and pH-sensitive block.

The interactions of protein subunits with a low aspect ratio (width over length) of spherical viruses (*e.g.*, HIV) lead to hierarchical self-assembly of the genome. By imitating the emblematic feature, a functional spherical artificial virus was constructed for endosomal escape.[109] In the presence of DNA, the interactions between synthetic polypeptides lead to the formation of the shell-like viral structure wrapping the DNA inside. The binding peptides progressively cleave and release the genome in response to pH regulation. Inspired by this, Ni *et al.* assembled 22 well-designed amino acid peptides into homogeneous nanodiscs (≈7 × 7 × 4 nm) by simulating the formation process of viruses (Fig. 5D).[110] Briefly, in this structure, the peptide chains along the DNA backbone drive the peptides to assemble into nanodiscs. Meanwhile, hydrophobic interactions facilitate the binding between the nanodiscs, allowing DNA to be encapsulated in multilayered nanostructures. At pH 5.0, the diminishing protonation of the two histidines destroys the interaction between the nanodiscs and the peptides, thereby releasing the cargo.

6. Nuclear targeting

A practical vehicle for realizing nuclear drug delivery should be able to protect drugs from degradation by the cytoplasmic enzymes and allow specific transport through the nuclear pore complexes (NPCs).[111,112] Among various nuclear delivery strategies, the so-called "Trojan horse" strategy inspired by viral infection is a representative example of efficient cytoplasmic delivery and nuclear targeting.[113] This section describes several virus-inspired nuclear targeting strategies for drug delivery.

After escaping from the endosome, some drugs/carriers still need to pass through the cytoplasm before reaching the nucleus.[114,115] Inspired by the assembly kinetics of TMVs, baculovirus-like nanosystems with the TMV capsid protein were developed by a polypeptide-based self-assembly strategy (Fig. 6A).[116] By locking the gene in artificial virus proteins, the nanosystems protected the DNA inside the carrier from being broken down by enzymes. Surprisingly, this study showed that the synergistic self-assembly process was highly similar to viruses. In another study, inspired by the stable structure of parapoxvirus, Ni *et al.* constructed a nanococoon system by co-assembly of 16 amino acid peptides with plasmid DNA.[117] It appeared as a virus-like ellipsoid (65 × 47 nm) with repeated fringes approximately 4 nm wide. The co-assembly process used DNA as a template to combine with the peptide chain through electrostatic interaction. Meanwhile, the double-layer β-folding and its lateral association stabilize the peptide capsid and DNA in it. As a result, the nanococoon protected peptides and DNA from enzyme digestion. To achieve the goal of passing through NPCs, nuclear localization signals (NLS) are widely used for effective nuclear localization.[118,119] By mimicking HIV and simian virus 40 (SV40), Kong *et al.* synthesized bioactive peptide-based nanocarriers pVLPs for delivering genetic cargo (Fig. 6B).[120] The nanocarriers were co-assembled with DNA by electrostatic interaction between two kinds of peptides: cell-penetrating peptides with membrane penetration ability and viral peptides with nuclear targeting capability. The results showed that the NLS (PKKKRKV) of SV40 could accurately deliver the cargo to the nucleus. Similarly, the virus-mimetic light-induced nanosystems for tumor therapy were reported in another study (Fig. 6C).[121] The nanocarriers were composed of PEI/DNA (PD) and a modular envelope (CCPNR). The study indicated that the PD@CCPNR system could effectively achieve nuclear targeting. Besides, a citraconic anhydride-modified nuclear signal-functionalized module further enhanced the gene delivery efficiency and improved the combined efficacy of photodynamic therapy. In short, compared with other conventional nanocarriers, the virus-inspired nanosystems (VINs) with viral polypeptides have the ability to protect the cargo from degradation and realize excellent nuclear targeting delivery. In addition, some viruses, such as AD and SV40, can recruit molecular motors near the nucleus by hijacking cell microtubule transport systems.[122] Recently, inspired by this process, VINs containing modular recombinant T-Rp3 proteins have been constructed to deliver nucleic acid cargoes, including plasmid DNA and SiRNA (Fig. 6D).[123] After the successful endosomal escape of VINs, T-Rp3 protein interacted with intracellular dynein and approached the NPCs.

7. Conclusions and perspective

For several years, by simulating the subtle structure of viruses, a number of nanosystems with excellent biocompatibility and

high delivery efficiency have been designed and constructed. In this review, we outlined and summarized the latest progress of virus-inspired nanosystems (VINs) from the perspective of various biological barriers that need to be overcome for successful targeted drug delivery. Undoubtedly, these unique types of nanosystems provide intelligent strategies for targeted drug delivery, which broaden the application of nanotechnology for biomedicine.

Although the advances in VINs have great potential in the study of targeted drug delivery, several challenges must be overcome before their further translation into clinical applications. The most crucial problem is biosafety. The prolongation of the circulation time of VINs contributes to the accumulation of carriers at the desired site, increasing the effectiveness of the drugs, but it also results in some other unsatisfactory consequences.[124] On the one hand, non-specific drug distribution due to prolonged half-life will cause new toxic effects or exacerbate adverse reactions. On the other hand, the increase in the metabolism of medicines by the liver and the kidneys might be higher than the drug accumulation in the target tissues. To solve this problem, the pharmacokinetics of drug carriers *in vivo* should be reconsidered comprehensively. A better strategy is to increase the blood circulation of the drug while increasing its selective activation properties.[125] Moreover, the immune response caused by viruses is a double-edged sword.[126] The virus-induced immune response is somehow helpful for killing cancer cells, but an excessive immune response can also cause great harm to the body. Under a good balance, VINs that combine viruses with immune cells could be developed for synergistic cancer therapy.

Further improvement of the delivery efficiency of VINs could be another significant challenge. The microenvironment inside and outside the cell membrane throughout the drug delivery process poses a dilemma for carrier design. For example, in most cases, the surface charge must be shielded to prolong circulation time. For another, the disassembly activity must be restrained to stabilize the drug in the extracellular environment. To overcome this difficulty, a more comprehensive understanding of simulating the virus infection process to release the genome or drugs in a stable manner is urgently needed. For instance, one good strategy is to develop spatiotemporal controllable VINs by integrating multiple viral structures with the help of external or endogenous stimuli such as light, ultrasound, enzymes, *etc*.

Due to the variety of direct biological responses that underlie virus entry into cells, cargo transport, and viral DNA replication, there are particular challenges for constructing life-like "viruses" that have universal applications. To extend the "pertinence" of viral infection to the "universality" of VIN development, testing different viral components under the basic principles is necessary. It is noteworthy that the construction of a peptide platform may allow the viroid components to display much functional diversity, extending the virus's specific infection ability. In addition, compared with the research on VINs for enhancing cellular uptake, there are few studies on nuclear targeting. In view of the importance of gene therapy, it is worth studying how to develop more nuclear targeting agents by using the nuclear targeting mechanisms of viruses.

Although VINs still face complex problems in the translation to clinical applications, we believe that, by learning from the viral infection process, utilizing the inherent merits of the viral structure, and the rational design of nanocarriers based on advances of nanotechnology, these difficulties could be overcome eventually. We predict more successful virus-inspired attempts for drug delivery shortly, which may open a bright path and expand the application of VINs in biomedical fields.

Abbreviations

ACE	Angiotensin-converting enzyme
AD	Adenovirus
AMT	Adsorptive-mediated transcytosis
Ang-I	Angiotensin I
AT1r	Ang-II type-1 receptor
ATMV	Artificial tobacco mosaic virus
BBB	Blood–brain barrier
CNS	Central nervous system
MSN	Mesoporous silica nanoparticles
NLS	Nuclear localization signals
NPCs	Nuclear pore complexes
NPs	Nanoparticles
PEI	Polyethylenimine
PAMAM	Poly(amidoamine)
PLA	Polylactic acid
PLGA	Polylactic-co-glycolic acid
RMT	Receptor-mediated transport
RABV	Rabies virus
TMV	Tobacco mosaic virus
VINs	Virus-inspired nanosystems
VIPER	Virus-inspired polymer
SV40	Simian virus 40
