Osteoimmunity is an interactive schema by which organisms maintain bone homeostasis. It permeates bone remodeling in healthy or diseased states, such as osseointegration of an oral implant material–alveolar bone socket or inflammatory osteolysis at the plaque–oral tissue–implant material interface. Once the self-mobilized osteoimmune system is insufficient to resist the spread of infection or inflammation caused by progressive periodontitis, smoking, or diabetes, peri-implant bone homeostasis will be tilted toward inflammatory osteolysis, as evidenced by an inflammatory response, osteoblast suppression, and osteoclast hyperactivity. Therefore, in addition to etiological treatment, harnessing osteoimmunity to enhance bone homeostasis stability and tissue anti-inflammatory capacity has also become a therapeutic approach for peri-implantitis. Here, we extract therapeutic targets in terms of cellular, protein, epigenetic modification, ribonucleic acid (RNA), and podosome-related osteoimmune mechanisms in inflammatory osteolysis, summarize the existing bioactive materials, implant surface modification, extracellular vesicles and other bioengineering techniques using osteoimmunity in the treatment of inflammatory bone loss, and look at potential targets for harnessing osteoimmunotherapy in peri-implantitis.

1. Introduction

Osteoimmunity involves interactions between the skeletal and immune systems to regulate the bone microenvironment. The balance between the skeletal and immune systems is disturbed in the face of sudden implant placement in a traumatic manner, which inevitably imposes an osteoimmune burden. Under normal circumstances, osteoimmunity can tolerate and develop a bone shield-off reaction in the form of interface bone.¹ Once the stimulus exceeds the osteoimmunity tolerable range, rejection reactions such as marginal bone loss will

progress until the osteoimmunity burden subsides.² Therefore, it has been argued that implants that remain stable in the alveolar bone which is a lifelong remodeling part of the skeletal system and consistently suffering occlusal stress should not be considered inert biomaterials. Instead, they should be classified as osteoimmunomodulatory and co-participate in the process of alveolar bone remodeling.³ If bacterial plaque micro-organisms cause hyperimmune rejection, the implant will transition from being osteoimmunomodulatory to being targeted by the immune system. This may lead to inflammation and osteolysis around the implant. Unlike inflammatory bone metabolic diseases caused by autoimmune disorders, periodontitis or peri-implantitis begins with polymicrobial synergy and dysbiosis.⁴ Additionally, distinct from periodontitis, osteoclast differentiation-related pathways are relatively more active in peri-implant inflammation, with a higher ratio of a receptor activator of a nuclear factor kappa-B (NF- κ B) ligand (RANKL)/osteoprotegerin (OPG).⁵ Classical osteolysis begins with the induction of mononuclear macrophages by RANKL and a macrophage colony-stimulating factor (M-CSF), followed by a gradual process of cell fusion and cytoskeletal reorganization to achieve osteoclast maturation and subsequent acquisition of bone resorption capacity.⁶ During inflammation, tumor necrosis factor (TNF) and interleukin-6 (IL-6) can contribute to osteoclast differentiation even without RANKL. This mechanism appears to be specific to inflammatory osteolysis.⁷ In

addition to the direct role of the RANKL-RANK-OPG axis, bone homeostasis is also indirectly and synergistically regulated by immune cells, such as macrophages, dendritic cells, and neutrophils.^{8,9} In conclusion, inflammatory factors secreted by immune cells aggravate the progression of infectious peri-implantitis. The process continues until inflammation subsides and bone homeostasis is restored. After this, osteoimmunity continues to drive bone repair and re-establish bone homeostasis.

To prevent peri-implant inflammatory osteolysis, intact and healthy soft-tissue integration is the first barrier.¹⁰ Signals from an impaired soft-tissue barrier can elicit an osteoimmune response. The implant itself may also induce an autoimmune response. Implant-derived titanium ions may enhance the Toll-like receptor 4 (TLR4)-mediated inflammatory response and increase the RANKL-OPG ratio, leading to inflammatory osteolysis.¹¹ Unlike reactive oxygen species (ROS)-induced cellular inflammation, titanium dioxide particle-induced inflammation^{12,13} does not depend on reactive oxygen species but on the acetylation of histone H3 lysine 56 (H3K56), causing DNA damage (early DNA damage marker – elevated γ H2AX).¹⁴ Any biomaterial that wishes to act on the host to cure or ameliorate a disease faces the threat of autoimmune rejection. It is essential to modulate the host's immune microenvironment in response to the biomaterial and harness it toward an ideal, favorable, and stable bone microenvironment, which is also called “osteoimmunomodulation” of bone regeneration.¹⁵ Bioactive materials such as polymers, ceramics, metals, monolithic architected composites, microporous nanoparticles, fibrous hydrogel networks, and 3D printed scaffolds directly recruit endogenous immune cells and stem cells for tissue healing and regeneration.¹⁶ In addition, bioactive materials that mediate bioelectricity also have a modulating effect on osteoimmunity due to the active bioelectrical properties of the bone tissue, such as the piezoelectric, pyroelectric, and ferroelectric charges mediated by collagen fibrils as well as the electro-osmosis and streaming potential present in bone tubules and laminae. The separation of hydrogen bonds between hydroxyapatite (HA) and collagen also plays a role.¹⁷ Similarly, the use of implant surface modification and extracellular vesicles can also help in the treatment of osteoimmune-mediated osseointegration to inflammatory immune-mediated osteolysis.

Understanding the causes of inflammatory osteolysis and the unfavorable bone microenvironment in which it occurs is a central aspect of understanding potential targets for treating osseointegration failure. This review provides an overview of advancements made in treating inflammatory osteolysis. It describes the viable approaches and prospects of osteoimmunomodulation in treating peri-implant inflammatory osteolysis regarding implant surface modification, bioactive materials, and extracellular vesicles.

2. Cascade of osteolysis reactions

2.1. The cytological process of osteolysis

There is always a dynamic combination of bone loss and bone regeneration in the bone microenvironment in terms of

catabolism and anabolism. The skeletal microenvironment is regulated by the involvement of the skeletal and immune systems through the interaction of bone marrow-derived mesenchymal stem cell-derived osteoblasts and bone marrow-derived hematopoietic stem cell-derived immune cells, which regulate osteogenesis and osteolysis (Fig. 1).

Bone marrow-derived mesenchymal stem cells

Growth factors such as insulin-like growth factor-I (IGF-I) and transforming growth factor (TGF) promote osteoblast proliferation. Meanwhile, the bone formation protein (BMP) and Wnt signaling-mediated transcription factors, like Runt-related transcription factor 2 (Runx2) and osterix (OSX), promote osteogenic differentiation.¹⁸ As bone formation progresses, mature osteoblasts adhere to the surface of the bone matrix and produce protein-like type I collagen (COL1). This contributes to osteoid formation, which is then calcified through the secretion of matrix vesicles and alkaline phosphatase (ALP).¹⁸ The integrity of the mature bone structure is maintained through the process of osteoclastic resorption and osteoblastic reconstruction, which involves the continuous development of both osteoblasts and osteoclasts. M-CSF and RANKL turn on the differentiation of monocyte-macrophages toward osteoclast differentiation, while the nuclear factor of activated T cells 1 (NFATc1) controls the terminal differentiation of osteoclasts.¹⁹ As they mature, osteoclasts release both protons (H^+) and enzymes that break down the bone matrix, including cathepsin K (CTSK) and matrix metalloproteinases (MMPs). These processes lead to the decalcification of bones and the degradation of proteins. Osteogenic inhibition and osteoclast induction are mainly triggered by two substances secreted by osteocytes: sclerostin and RANKL, respectively.²⁰ After being cocultured with osteocytes, osteoclast precursor cells displayed more powerful ability to induce osteoclasts. Specifically, their ability to express RANKL was much higher than that of osteoclasts cocultured with osteoblasts, up to tens of times higher.²¹ In the maturation phase of bone growth, osteocytes have a greater advantage in OPG expression than osteoblasts.²² This makes osteocytes incredibly important in the bone microenvironment as they regulate the balance between osteogenesis and osteolysis. There is a lack of studies that target osteocytes to induce osteogenesis during the early stages of osseointegration and osteoclastogenesis during bone remodelling. Such temporal and sequential targeting of osteocytes for the regulation of bone homeostasis would be a major challenge.

Bone marrow-derived hematopoietic stem cells

Among immune cells, T lymphocytes express minimal levels of RANKL and have little involvement in osteolysis, similar to B lymphocytes.^{23–25} However, the absence of T/B lymphocytes can negatively impact bone health. This is because B lymphocytes produce less IL10, which reduces the bone microenvironment's ability to repair inflammation effectively.²⁶ On the other hand, patients with periodontitis had a significantly higher percentage of CD4⁺ T helper (Th) cells, such as Th1 and Th17 cells, accompanied by a high expression of inflammatory infiltrative

Fig. 1 The triad of bone marrow mesenchymal stem cells, hematopoietic stem cells, and osteocytes regulates the processes of osteolysis and osteogenesis. (Note: the green upper triangular section represents osteogenesis, while the lower red triangular area represents osteolysis.)

factors and an increase in the number of osteoclasts.^{27,28} Similarly, research has found that IL-6 can significantly promote the differentiation and maturation of dendritic cells (DCs), which can ultimately contribute to the progression of periodontitis.²⁹ Mature DCs bidirectionally regulate bone homeostasis, eliciting osteoprotective and osteodestructive responses by activating and inactivating FoxO1, respectively.⁸ DCs help in activating Th1 cells by releasing IL-12 and interferon- γ (IFN- γ), and they promote the differentiation of Th17 cells by releasing TGF- β , IL-6, IL-23, and IL-1 β . These cascades of amplified signals continue to sustain the inflammatory response and osteoclastic induction in response to RANKL activation.^{30–32} Alternatively, DCs can induce regulatory T-cell (Treg) responses by secreting IL-10 and TGF- β to resist the further development of inflammatory osteolysis.³³ Triggered by *Porphyromonas gingivalis* (Pg) derived LPS, neutrophils over-express IL-4, with consequent initiation of IL4/IL4R/ERK signaling in CD115(+) osteoclast precursors (OCPs) to promote their proliferation and subsequent osteolysis.^{34,35} When phagocytes

remove exogenous inflammatory factors, the produced extra-cellular traps (NETs) are susceptible to mineralization of dental calculus, further stimulating inflammation and osteolysis. NETs secreted by neutrophils mediate TLR4 signaling and NET-associated proteins, including histones and neutrophil elastase, to induce rapid osteoclastogenesis, especially when NETs are carbamylated.⁹

In conclusion, in response to stimulation by inflammatory factors such as the LPS, antigen-presenting cells like DCs activate the proliferation and differentiation of Th1 and Th17 cells. This is followed by clearance of inflammatory stimuli by trending neutrophils and macrophages but also inevitable by tissue destruction due to high expression of RANKL and MMPs. At the same time as hyperinflammation, Th2 cells and Tregs also increase in number, differentiate, and release anti-inflammatory factors like IL-10. This helps to mitigate the harm caused by Th1 and Th17 cells and promotes the healing of damaged tissues. Targeted modulation of immune cells is not a substitute for etiological treatment that removes

exogenous antigens, but rather a way to assist in the amplification of intrinsic autoimmunity. Enhancing the efficiency of antigen presentation and antigen clearance, while directing the body towards tissue repair as soon as possible, will be the desired efficacy of immunomodulation in peri-implantitis.

2.2. Protein regulation of osteolysis

RANKL-OPG competition is the most direct and critical aspect of regulating osteogenesis and osteolysis. The development of osteoclasts and subsequent bone resorption are hindered by RANKL inhibitors.³⁶ The lack of OPG (an inhibitor of bone resorption that antagonizes RANKL-rank binding) will bring about bone loss so severe that it becomes one of the criteria for modeling spontaneous alveolar bone loss.³⁷ Based on this theory, denosumab is a competitive antagonist of RANKL that can effectively inhibit osteoporosis or tumor bone metastasis. However, in some patients, it may significantly increase the risk of osteonecrosis of the jaw after tooth extraction.^{38–40} This may be related to the inhibition of microvascular and immune mobilization by bisphosphonate. After partial elimination of inflammatory factors (inhibition of TNF- α , IL-1 α/β , or IL-6), however, the progression of osteonecrosis can be significantly inhibited.⁴¹ Thus, the role of osteoimmunity in bone protection is not only to maintain the osteoblast–osteoclast balance but also to activate osteoclasts to remove necrotic areas while suppressing inflammation to promote bone tissue repair during inflammatory infections (Fig. 2).

Role of MAPK/NF- κ B/c-Jun downstream of TRAF6 in the cytoplasm. In addition to RANK receptors, activation of Toll-like receptors (TLRs), IL1R, TNFR, and growth factor receptors (GFRs) also synergizes with the induction of inflammatory osteolysis by RANKL.⁴² Upon activation of RANK signaling, TNF receptor-associated factor 6 (TRAF6) autoubiquitinate to form nondegradative K63-linked ubiquitin chains, which recruit TGF-activated kinase 1 (TAK1)–TAK1-binding protein 1/2 (TAB1/2) complex formation.⁴³ RANKL-induced osteoclast differentiation is dependent on the activation of TRAF6 and TAK1, the deletion of which results in impaired activation of mitogen-activated protein kinases (MAPKs) and NF- κ B.^{44,45} In the MAPK signaling pathway, the c-Jun N-terminal kinase (JNK) protects osteoclast precursor cells from RANKL-induced apoptosis during differentiation and facilitates the formation and differentiation of RANKL-activated osteoclasts.⁴⁶ The inhibition of p38 interfered with osteoclast formation but had a little effect on the bone resorption effect of osteoclasts.⁴⁷ The osteoclast-inducing effect of MAPK extracellular signaling-regulated kinase (ERK) (MEK) remains controversial.^{48,49} Furthermore, when IKK γ is lacking, the transcription factor NF- κ B is unable to enter the nucleus, hindering the expression of genes related to osteoclast formation.⁵⁰ In the absence of JunB, there is a decrease in the number of osteoclasts, and this reduction is even more pronounced when c-Fos is also lacking.^{51,52} Reductions in both NF- κ B and activator protein 1 (AP-1) (composed of c-Fos and Jun proteins) in osteoclasts lead to osteosclerosis. Inhibition of cytoplasmic proteins downstream of TRAF6 may cause alterations in many cellular functions. Direct inhibition

of TRAF6 or cell membrane proteins may have more immediate efficacy, but the end points of the inhibitory effect need to be clarified to avoid toxic side effects of treatment.

Regulation of proteins in the nucleus. Osteoclast formation and survival are inextricably linked to the osteoclast-associated receptor (OSCAR), which is dependent on the transcriptional induction of the AP-1 complex.⁵³ Additionally, the AP-1 complex promotes the formation of bone resorption structures (actin rings and ruffled membranes) through the activation of integrin β 3.⁵⁴ Furthermore, the AP-1 complex contributes to the fusion of osteoclast precursor cells through the activation of the dendritic cell-specific transmembrane protein (DC-STAMP), osteoclast stimulatory transmembrane protein (OC-STAMP), and vacuolar-ATPase subunit d2 (V-ATPase).^{55–57} Osteoclastic differentiation requires NFATc1 as an essential component. Its activation relies on TRAF6, c-Fos, and p50/p52 NF- κ B.⁵⁸ Additionally, NFATc1 is responsible for mediating activating transcription factor 4 (ATF4), B lymphocyte-induced maturation protein 1 (Blimp1), leukemia/lymphoma-related factor (LRF), or Jun dimerization protein (Jdp2) to function.^{59–63} Moreover, the binding of NFATc1 to the AP-1 complex is also involved in TRAP transcription.⁶⁴ Secretory TRAP will act as a bone matrix resorber in the acidic environment between osteoclasts and the bone surface. However, immunotherapy against transcription factors also faces toxic side effects caused by a wide range of downstream regulatory sites. Addressing this issue is a major challenge.

Mitochondrial oxidative stress. Induced by inflammatory and osteolytic stimuli, nicotinamide adenine dinucleotide phosphate (NADPH) oxidase 4 (NOX4) in the mitochondrial electron transport chain generates large amounts of ROS and exacerbates the induction of inflammation and osteolytic differentiation by the transcription factors AP-1 (c-Jun/c-Fos), NF- κ B and NFATc1.^{65–67} The transcription factor nuclear factor-erythroid 2-related factor 2 (Nrf2) is a negative regulator of NOX4, preventing further development of oxidative stress and osteoclasts.⁶⁸ Meanwhile, the transcription factor FoxO induces catalase (CAT). This helps in regulating the excessive production of ROS and plays a negative regulatory role in hyperactive osteoclast differentiation.⁶⁹ Therefore, the development of mitochondrial-targeted drugs for Nrf2 and FoxO facilitates the stabilisation of the mitochondrial respiratory transport electron chain and the control of ROS overexpression, which is beneficial for the treatment of osteoblastic hyperactivity.

Calcium ion effect. In addition, RANKL-induced osteolysis is inseparable from Ca²⁺ migration. The G protein-coupled receptor (GPCR) and tyrosine kinase receptor (Trk) catalyze the hydrolysis of membrane phospholipid phosphatidylinositol^{4,5} bisphosphate (PIP2) upon inflammatory stimulation to produce diacylglycerol (DAG) and inositol triphosphate (IP3). DAG induces MAPK signaling to enhance c-Fos and NF- κ B expression. IP3 induces Ca²⁺ release from the endoplasmic reticulum, which subsequently activates the dephosphorylation of NFAT by calcineurin (CaN). As a result, NFAT can move into the nucleus and regulate genes on its own or in conjunction with transcription factors like AP-1.^{70–72} Additionally, in response to RANKL–RANK signaling, the calcium-activated

Fig. 2 The proteins secreted and pericytes present in the inflammatory osteolysis microenvironment can potentially influence the differentiation of osteoclasts.

chloride channel anoctamin 1 (Ano1) upregulates NFATc1 expression in response to intracellular Ca^{2+} activation and releases chloride ions that act in concert with the proton pump (H^+) for bone resorption.⁷³ The development of drugs targeting inhibition of the GPCR and Trk or downstream IP3 might be one of the feasible ways to inactivate intracellular calcium signalling and thus inhibit bone resorption.

2.3. Molecular modification of osteolysis

Upstream of the protein regulation of bone homeostasis, the surfaces of DNA, RNA, and histones play a role in signal transduction through modifications such as acetylation and

methylation. Differences in the regulation of epigenetic modifications can be identified through comparisons between healthy and diseased tissues. Histone deacetylases (HDACs) 1, 5, 8, and 9 and histone demethylase lysine demethylase 4B (KDM4B) were highly expressed in the gingival tissue of patients with periodontitis.⁷⁴ Meanwhile, HDAC inhibitors (HDACi) positively affect bone regeneration in periodontal tissues. Inflammatory osteolysis induced by Pg bacteria achieved bone regeneration with HDACi treatment, especially inhibitors of class I and class II HDACs.⁷⁵ In addition, the histone methyltransferase enhancer of zeste homolog 2 (EZH2) was able to upregulate the expression of VCAM-1, which leads

to the inhibition of miR-101 expression and subsequently suppresses periodontal inflammatory bone resorption.⁷⁶ Drugs targeting molecular modifications may hold promise for assisting bone immunomodulation.

Osteogenesis. Epigenetic modifications can tilt bone homeostasis toward osteogenesis. HDAC1 and HDAC2 are important regulators of osteogenic differentiation, with upregulation of osteogenic markers other than OCN.⁷⁷ Additionally, HDAC1 targets the promoters of genes responsible for the osteoclast function (e.g., NFATc1 and OSCAR) to impede their expression and suppress osteoclast differentiation.⁷⁸ Reducing the expression of HDACs 4, 5, 9, 10, and 11 leads to an increase in the size and demineralization activity of multinucleated giant cells. However, it has little impact on the total number of multinucleated giant cells formed.⁷⁹ HDAC6 is crucial in destabilizing the osteoclast skeleton, hindering osteoclast migration, and preventing the formation of podosomes.⁸⁰ HDAC7 inhibited the transcription of NFATc1, CTSK, and DC-STAMP to prevent osteoclast differentiation, but it also inhibited the maturation of osteoblasts.⁸¹ RANKL helps in keeping FoxO in an inactive state through pathways like phosphorylation. Meanwhile, sirtuin 1 (SIRT1) activates FoxO by deacetylating it and also reduces the levels of H₂O₂. This inhibits the increase and differentiation of osteoclasts.⁸² It was found that SIRT3 plays a role in maintaining mitochondrial homeostasis by deacetylating cytochrome *c* oxidase subunit 4 isoform 2 (COX4I2).⁸³ Additionally, SIRT6 was found to deacetylate STAT5, which inactivates IL-15/JAK3/STAT5.⁸⁴ These actions serve as negative regulators of the inflammatory response and RANKL-induced osteolysis. In osteoblasts, lysine-specific demethylase (LSD1) inhibits PBX1 translation to promote osteoblast differentiation. It positively regulates miR-6881-3p, which targets the inhibition of pre-B-cell leukemia homeobox 1 (PBX1) to promote osteogenic differentiation and the inhibition of additional sex combs like-2 (ASXL2) to inhibit osteoclastic differentiation.⁸⁵ Inhibition of the KDM4B expression causes compensatory activation of KDM1A, reducing the production of proinflammatory factors and osteoclasts.⁷⁴ Methyltransferase-like 3 (METTL3), the core methyltransferase that installs an N⁶-methyladenosine (m⁶A) modification on RNA, stabilizes the mitochondrial function by reducing the iNOS/NO expression, thereby inhibiting osteolysis under inflammatory conditions.⁸⁶ The above studies suggest that epigenetic modifications are feasible for the treatment of inflammatory osteolysis.

Osteolysis. Similarly, epigenetic modifications can tilt bone homeostasis toward osteolysis. HDAC3 promotes osteoclast differentiation, and its reduced expression can increase the induction of osteogenic differentiation.^{87,88} The p300/CREB-binding protein-associated factor (PCAF) induces osteolysis by acetylating H3K27 in the C-X-C motif chemokine ligand 12 (CXCL12) promoter region in osteoblasts.⁸⁹ It also acetylates NFATc1 in osteoclasts and runt-related transcription factor 2 (Runx2) in osteoblasts to simultaneously induce osteoclast differentiation and inhibit osteogenic differentiation.⁹⁰ The PCAF also activates Wnt5a to promote osteolysis.⁹¹ Differential recruitment of the histone H3K4 methyltransferase SET

domain containing 1A (SETD1A) leads to differential polarization of macrophages and osteoclasts.⁹² Enhancement of DNA methyltransferase will silence osterix (Ox) and prevent osteogenic differentiation.⁹³ The euchromatic histone lysine methyltransferase 2 (EHMT2) monomethylates H3K27 to H3K27me₁, which recruits MMP9 for proteolysis of the histone H3N-terminal tail (H3NT), thereby triggering osteoclast-specific gene expression.⁹⁴ EZH2 catalyzes the trimethylation of H3K27, which targets the Ndr2 promoter to inhibit osteoblast differentiation. It also promotes osteoclast differentiation, further exacerbating bone destruction.⁹⁵ Disruptor of the telomeric silencing 1-like protein (DOT1L), which catalyzes the trimethylation of H3K79, increases the level of ROS in osteoclasts and the ability of osteoclasts to fuse and osteolysis.⁹⁶ RANKL-induced osteoclast differentiation activates protein arginine methyltransferase (PRMT1/5) expression in a JNK-dependent manner, which methylates NF- κ B and induces osteoclastic formation and bone resorption.^{97,98} The H3K27 demethylase Jumonji domain-containing 3 (Jmjd3), activated at the transcriptional start site of NFATc1, responds to RANKL-stimulated osteoclastic induction by demethylating H3K27me₃.⁹⁹ In osteoclasts, LSD1 demethylates H3K4 and H3K9 to stabilize HIF- α , promoting osteolysis during RANKL-mediated osteoclast differentiation. However, LSD1 inhibitors do not affect methylation levels of H3K4 and H3K9 during the inhibition of osteolysis.^{100,101} Upon stimulation of the receptor activator of the NF- κ B ligand, the KDM4B-CCAR1-MED1 complex is localized to the promoters of multiple genes related to osteoclasts. This complex induces the formation of osteoclasts through the process of H3K9 demethylation. It leads to NF- κ B p65 recruitment *via* a direct interaction between KDM4B and p65.¹⁰² N⁶-methyladenosine (m⁶A) demethylase fat mass and obesity-associated protein (FTO) overexpression contribute to the transcription factor NF- κ B. This leads to an increase in the expression of osteoclast genes like NFATc1 when stimulated by RANKL.¹⁰³ The RNA methyltransferases METTL16 and FTO are osteodestructive factors, while YTHDF2, a recognition protein of m⁶A, is an osteoprotective factor.¹⁰⁴ But the lack of specificity for the gene site is the fatal weakness of epigenetic drugs.

2.4. RNA mechanism of osteolysis

Differences in RNA expression were found in oral fluid biomarkers of periodontitis and peri-implantitis. This is of potential value for diagnosing and treating inflammatory osteolysis around teeth or implants. For example, the upregulation of miRNA-142-3p and miRNA-146a is representative in diagnosing periodontitis.¹⁰⁵ MicroRNAs, including miR-let-7g and miR-27a, show a significant increase in peri-implantitis cases, contrasting with the dramatic decrease observed in miR-145.¹⁰⁶ These findings suggest that these microRNAs could potentially aid in the development of effective treatments for inflammatory osteolysis in the future.

MicroRNAs. MicroRNAs are involved in osteoclast differentiation in inflammatory osteolysis. The oral inflammatory environment will lead to high expression of hsa-miR-374b-5p.

This can then lead to the inhibition of U2AF homology motif kinase 1 (UHMK1), ultimately increasing osteoclastic differentiation.¹⁰⁷ The negative regulation of RUNX1 by miR-28 favors osteoclast differentiation, while its deletion causes a decrease in the number of osteoclasts.¹⁰⁸ MiR-21 inhibits programmed cell death 4 (Pdc4) expression, which in turn rescues the inhibition of c-Fos by Pdc4 and thus promotes inflammatory osteolysis.¹⁰⁹ In addition, miR-21 is also involved in the activation of T cells and stimulates their secretion of RANKL.¹¹⁰ MiR-182 targets FoxO3 and mastermind-like transcriptional coactivator 1 (Maml1) to promote TNF- α -induced inflammatory bone resorption but is inhibited by the recombination signal binding protein for the immunoglobulin kappa J region (RBP-J).¹¹¹

MicroRNAs are also involved in autoimmune repair of inflammatory osteolysis. MiR-29a reduces the secretion of RANKL and CXCL12 by osteoblasts and plays an osteoprotective role.⁸⁹ MiR-142-3p has a significant inhibitory role in the differentiation of monocytes/macrophages/dendritic cells into osteoclasts. Depending on RANKL activation, miR-142-3p targets and promotes the high expression of protein kinase C- α (PKC- α), which in turn induces the apoptosis of osteoclasts and facilitates the arrest of osteolysis progression.¹¹² Similarly, negative regulation of C-X-C motif chemokine receptor 2 (CXCR2) by miR-155-5p hinders osteoclast differentiation.¹¹³ Overexpression of miR-335-5p and miR-218 inhibited inflammatory osteolysis in the alveolar bone.^{114,115} MiR-1260b inhibits Wnt5a and ATF6 β expression, impairing RANKL pathway-mediated osteoclastic activity. Human gingiva-derived MSC (GMSC) derived exosomes containing miR-1260b are beneficial in the treatment of bone loss in periodontitis.^{116,117} Unlike siRNA and protein targeted drugs, miRNA's mimetics and inhibitors have poor specificity, which also leads to limited clinical applications.

Long noncoding RNAs (lncRNAs). lncRNA acts as an antagonist of microRNA, inhibiting the binding of microRNA to messenger RNA (mRNA) and exerting immunomodulatory effects. The lncRNA differentiation antagonizing nonprotein coding RNA (DANCR) positively regulates the expression of Jagged1 and promotes osteoclast differentiation.¹¹⁸ The lncRNA noncoding repressor of NFAT (NRON) effectively promotes the nuclear translocation of the NF- κ B repressing factor (NKRF), preventing NF- κ B from activating the transcription of NFATc1. This can ultimately lead to a reduction in bone resorption for patients with periodontitis.¹¹⁹ It was found that miR-221-5p prevented the activation of NF- κ B and the resulting osteoclastic differentiation by CXCR3-CXCL10. However, the osteoclast-specific lncRNA (OC-lncRNA) countered miR-221-5p by sponging it, which led to osteolysis.¹²⁰ lncRNA metastasis-associated lung adenocarcinoma transcript 1 (MALAT1) competitively binds miR-124 to inactivate the latter's inhibitory effect on NFATc1 expression, thus promoting the development of bone loss in periodontitis.¹²¹ Endogenous antagonists of mRNA or miRNA in the development of oral inflammatory bone diseases may be the key to future inflammatory regulation and osteolysis treatment in the oral environment.

2.5. Progression of podosomes to osteolysis

Formation of podosomes. Podosomes, which function to degrade the extracellular matrix (ECM), are found in cells such as monocytes, macrophages, osteoclasts, and migratory dendritic cells.^{122–125} It is involved in physiological processes, including cell migration, bone remodeling, and angiogenesis.^{126–128} Unlike podosomes in macrophages or dendritic cells, which are dispersed on the ventral adhesion side or at the tip of the migration direction, podosomes gradually evolve from clusters and rings to belts (on glass) or sealing zones (on bone) during osteoclast development.¹²⁹ The β 1 and β 3 integrins that provide the ECM attachment,¹³⁰ RhoA-inactivating proteins like p190RHOGAP,¹³¹ and reduced local contractility¹³² constitute the three elements of podosome formation. RhoA knockout mice and corresponding RhoA-deficient primary macrophages exhibit impaired bone resorption and osteoclast induction. On the other hand, high levels of RhoA can activate Akt-mTOR-NFATc1 signaling, leading to the promotion of osteoclast development.¹³³ Phosphatidylinositol 3,4-bisphosphate (PtdIns (3, 4) P2) and PI3K-induced PtdIns (3, 4, 5) P3 accumulate at the podosome formation site and recruit WASP and TKS5 to participate in the formation of the core and cap of the podosome, respectively.¹³⁴ Myosin IIA, together with regulators such as LSP1, induces the generation of oscillatory protrusions that release hydrolases such as MT1-MMP.¹³⁵ The podosome has ARP2/3 complex-mediated branched F-actin as its core with a cap-like structure consisting of cross-linked F-actin and bundled F-actin at the head and surrounded by a ring of adhesion proteins attached to the ECM *via* integrins at the tail. The middle-exposed region is present with the transmembrane protein membrane-type metalloproteinase-1 (MT1-MMP) and cell surface adhesion receptor CD44, which are directly involved in the regulation of ECM degradation by hydrolases.¹²⁹ With the help of calpain-induced WASP cleavage, the supervillin further completes the degradation of the podosome.¹³⁶ A disintegrin and metalloproteinase (ADAM) 17 mediates the shedding of membrane-bound cytokines and corresponding membrane proteins. *In vivo* and *in vitro* experiments enhancing ADAM 17 activity significantly increased LPS-induced shedding of TNF- α and TNFRII in macrophages while activating TLR-mediated podosome disassembly, synergistically disrupting cell migration and invasion capacity¹³⁷ (Fig. 3). The treatment method of intervening in podosome formation can inhibit the osteoclast function, but further clinical trials are needed to test its safety.

Functional proteins of podosomes. Podosomes' formation, maturation, and transformation are inseparable from CDC42, RAC, and Ras homolog (RHO) in RHO GTPases, respectively. *In vitro* and *in vivo* experiments with knockdown or inhibition of RAC1 and RAC2 have demonstrated the indispensable importance of RAC1/2 in the formation of the sealing zone of osteoclasts.^{138,139} RHO interferes with the fusion of the podosome ring to the belt at an early stage of osteoclast differentiation.^{140,141} Rho or its activating effector mDia2 reduces the level of microtubule acetylation in the podosome structure by activating HDAC6, bringing about the structural and functional defects in the podosome and impairment of osteoclast differentiation.¹⁴⁰ Targeted protein therapy to

Fig. 3 The process of how podosomes interact with the extracellular matrix on the cell membrane surface.

prevent podosome maturation and accelerate podosome decomposition is theoretically feasible, but further animal and clinical trials are still needed to validate it.

Podosomes during bone resorption. RANKL triggers macrophage podosomes to migrate inward, extending actin-rich protrusions that facilitate fusion with neighboring cells. The fused macrophages are filled with actin-rich zipper-like structures to complete cell-cell junctions.¹⁴² Mature osteoclasts adhere firmly to the ECM through the adhesion rings of the podosome and CD44 below the nucleus, with dense podosomes arranged closely inside the giant osteoclast membrane to form a closed zone for bone resorption.¹⁴³ Osteoclasts on the bone surface produce a more expansive sealing zone and a higher density of podosomes than in flat, smooth glass.¹⁴⁴ The ruffled border of osteoclasts on the bone has a denser actin fiber network than that in calcite.¹⁴⁴ In the collagen-rich environment, type I collagen fibers will activate a linear podosome that is anchored to the ECM in a structure containing not integrins but discoidin domain receptor 1 (DDR1) with IRhoGTPase-Cdc42 and its specific guanine nucleotide-exchange factor (GEF)-tuba structure.¹⁴⁵ In addition to regulating the degradation of the ECM by hydrolases, the podosome in macrophages also has a role in recruiting deoxyribonuclease (DNase) to degrade extracellular or bacterial DNA.¹⁴⁶ The podosome within macrophages releases MMP2 and MMP9.¹⁴⁷ However, relying on hydrolytic enzymes and lacking an acidic environment, or having difficulty breaking the disulfide bonds between

fibers, makes it challenging to degrade the ECM completely. We have not yet explored the role of the Na^+/H^+ exchanger NHE1, which mediates the acidic environment, and oxidoreductase, which reduces disulfide bonds, in the degradation of the ECM by podosomes.

3. Bioengineered treatment of osteolysis

3.1. Electrobiomaterials

Electrobiomaterials favor bone remodeling. Appropriate mechanical stress and exogenous electrical stimulation can enhance bone remodeling and osseointegration of bone grafts with autogenous bones.¹⁴⁸ Piezoelectricity in collagen fibers, fluid-generated streaming potentials in bone microtubules and the flexoelectric effect in cortical bones are important electro-mechanical foundations for harnessing bone remodeling.^{149,150} Hydroxyapatite significantly induced osteogenic differentiation after electropolarization treatment, while electropolarized synthetic carbonate-substituted apatite scaffolds also improved osteoclastic resorption through increased interfacial wettability.¹⁵¹ Combining the tricalcium phosphate gelatin scaffold with electroacupuncture stimulation (ES) induced a pH change in the culture medium. This resulted in the activation of osteoclasts and osteoblasts in coculture systems, leading to bone formation in rats with bone defects.¹⁵² The

simultaneous activation of osteoclastic and osteoblastic activities by electrical stimulation will facilitate the *in situ* remodeling and fusion of bone graft materials with autogenous bones to accelerate the regenerative repair of bone defects.

Electrobiomaterials favor restoration of the bone electrophysiological microenvironment. Physiological movements such as standing and walking will generate a piezoelectric negative potential of about 300 μV , which is considered to be an electrophysiological environment favourable for osteocyte activity and maintenance of bone homeostasis. Higher electronegativity and currents of 1–10 $\mu\text{A cm}^{-2}$ occur at fracture and wound healing sites.¹⁵³ The electrophysiological microenvironment required for bone transformation under disease conditions will be significantly altered. The electrobioactive material aims to mimic the natural electrophysiological microenvironment of healthy bone tissue. This is achieved through various exogenous stimuli such as dielectric, piezoelectric, and pyroelectric properties. The material also generates spontaneous ferroelectric, electroosmotic, and flow potentials to promote osteogenic and angiogenic effects while also having anti-inflammatory, anti-osteolytic, and antibacterial properties for therapeutic purposes. Immunomodulation of biomaterials in inflammatory osteolysis lays the foundation for osteogenic induction. Immunomodulation in electroactive scaffolds is manifested in the chemotaxis of immune cells by electrical stimulation to reduce inflammation and improve a bone microenvironment conducive to tissue regeneration. Monocytes and macrophages tend to avoid electrical stimulation, thus reducing the levels of inflammatory cells and corresponding proinflammatory cytokines in the electrical environment.¹⁵⁴ In addition, there is an electric field-dependent regulation of phagocytosis by macrophages. With the aggregation of phagocytic receptors, activation of phosphoinositide 3-kinase (PI3K) and extracellular regulated protein kinases (ERK), mobilization of intracellular calcium, and polarization of actin, macrophages induce the enhanced phagocytosis of microorganisms and necrotic cells, which is crucial for tissue debridement, as well as subsequent osteogenic induction and osteoclastic remodeling.¹⁵⁵ Self-promoting electroactive mineralised scaffolds induce osteogenesis by activating voltage-gated channels and relying on the electroactive surface of the material to inhibit bacterial adhesion.¹⁵³ Time-sequential modulation of electrical stimulation using a fully biodegradable piez-triboelectric hybrid nanogenerator lays the foundation for future treatment of abnormal electrophysiological environments in disease settings.¹⁵⁶ In addition to conductive biomaterials (carbon-based nanomaterials, metallic conductive materials, and conducting polymers) that can be stimulated by exogenous power sources, nanogenerators, such as piezoelectric materials, can also rely on mechanical force conduction. Similarly, materials with superior optoelectronic properties like Mxenes can be stimulated by light of different wavelengths and penetration depths,¹⁵³ which are expected to produce time-sequential modulations that can intervene in the functioning of tissues and cells.

Bioelectric synergies favor inflammatory osteolysis treatment. Bioelectrical activation can be used alone or in synergistic

pairings to achieve microenvironmental modulation. A vaccine technology that uses electrical stimulation to program autologous dendritic cells may be able to enhance the dendritic cell expression of FoxO1, inducing its anti-inflammatory regulatory role in the context of osteoimmune.¹⁵⁷ Electrical and chemical excitation of membrane-covered porous titanium scaffolds have anti-inflammatory and osteogenic differentiation-inducing efficacy.¹⁵⁸ Photosensitive graphene materials can promote osteogenic differentiation by altering the surface potential distribution and activating voltage-gated calcium channels through visible light stimulation.¹⁵⁹ The above materials combine chemical effects or visible light to synergistically stimulate osteoimmune homeostasis in inflammatory environments. Researchers could continue to fill in the gaps between the electrical stimulation and the modulation of tissues and cellular features by various physical properties, such as magnetism, temperature, and force. In addition, future developments should also focus on the time-sequential treatment of inflammatory osteolysis, relying on time-sequential changes in the magnitude of pulsed electrical energy to modulate the immune/osteogenic process accordingly.

Diabetes, with its high glucose and oxidative stress hyperactivity, contributes to the severity and persistence of microbial attack and corresponding tissue damage. The use of chitosan or nanoparticles to create a biomimetic electro-microenvironment has been found to induce anti-inflammatory changes in M1 macrophages under high glucose conditions. This is achieved through the inhibition of protein kinase B (AKT2) and interferon regulatory factor (IRF5) expression in the PI3K-AKT signaling pathway. Additionally, these bioelectric synergies enhance the osteogenic differentiation of human bone marrow mesenchymal stem cells (BMSCs) in a coculture environment, leading to a beneficial osteoimmune microenvironment.^{160,161} Positive charge treatment of the drug delivery system achieved anti-inflammatory transformation and effectively promoted wound healing in diabetic mice.¹⁶² By combining the electrical conductivity of graphene oxide, the osteoconductivity of polarized hydroxyapatite, and the anti-inflammatory properties of polydopamine, researchers have created active scaffolds that can significantly enhance bioelectrical signals. These scaffolds have shown the potential to promote bone regeneration in periodontal bone defects in diabetic rats.¹⁶³ However, there is still a lack of clinical evidence to support the use of electrobiomaterials to modulate the bone microenvironment in diseases. The reasons for limiting clinical studies of electrobiomaterials may lie in the stability and safety of the electrical output of these electro-active materials, the long-term biosafety and the metabolic toxicity of degradable conductive polymers.

3.2. Implant surface modification

From osteogenesis to antibacterial properties. The surface of titanium can vary in several ways, including roughness, microscopic discontinuities, hydrophilicity/hydrophobicity, chemistry, and electrical charges. Such differences can significantly impact proteins, cells, and bacterial adhesion, which in turn affects the success of osseointegration and continuous bone remodeling. The ideal implant surface should have adhesive

properties that are antimicrobial but favorable for cell adhesion, thus giving rise to the development of various antimicrobial coatings.

Osteogenesis. Enhancing the osseointegration of titanium implants initially focused on the physical or chemical modification of the surface morphology. Physical surface protrusions are known to play an important role in the survival of bacteria and cells and in their functional differentiation. Nanopillar arrays of 200 nm were able to induce osteogenic differentiation in human adipose-derived stem cells (hADSCs) and induce ectopic osteogenesis *in vivo*.¹⁶⁴ Drawing on the structural properties of nanopillars, hollow titanium oxide TiO₂ nanotubes synergised with releasable co-doped calcium or/and strontium can significantly enhance osteogenic properties.¹⁶⁵ The prominence of the nano/micron structure to modulate bioactivity actually stems from the high degree of biomimicry of the material to the natural extracellular matrix of the host bone and bone healing hematoma. These bionic micro- and nanostructures on the implant surface will result in increased osteogenic and angiogenic activity of BMSCs and vascular endothelial cells and generate an anti-inflammatory predominantly osteoimmune microenvironment.¹⁶⁶ To further improve biocompatibility, a team prepared a hybrid coating of titanium phosphate and TiO₂, where protein adhesion and the activity and osteogenic function of BMSCs were significantly enhanced and followed by stronger bone-implant contact bond strength.¹⁶⁷ When TiO₂ is doped with weaker Zn–O bonds, the superiority of osseointegration and the ability of Zn²⁺ release with subsequent ROS for bacterial killing will be balanced well, promoting the osseointegration of tibiae of rats infected with *Staphylococcus aureus*.¹⁶⁸ Combining physical protrusion structures that facilitate osteogenesis with surface coatings that enhance biocompatibility and/or improve antimicrobial properties is one of the future directions for solving the difficulties of osseointegration of implants in a bacterial environment.

Antibacterial. In the field of biomimetic physical antimicrobials, physical nanoprotusions on insect wings are mimicked to be able to penetrate or stretch bacterial cell walls to provide contact-killing antimicrobial effects. Rough structures of 10–100 µm formed by sandblasting or 1–3 µm formed by acid etching do not have the antimicrobial properties exhibited by nanostructures of 100–250 nm, as evidenced by bacterial penetration and envelope deformation ratios.^{169,170} And different levels of roughness have corresponding differences in the cell viability and function. Similar to the micron-sized rough surface obtained by sandblasting and acid etching, the nanomorphology after alkali-hydrothermal treatment was superior to the smooth titanium surface in promoting osteogenic activity. Moreover, the attachment of nanomorphology to the gingival epithelium was superior to that of smooth titanium surfaces.¹⁷¹ This suggests that hard and soft tissue closure may not require the clinically typical segmented implant with a smooth neck and rough body. One-piece nanoimplants are theoretically

sufficient for a satisfactory hard and soft tissue closure. Moreover, nanotubes with an inner diameter of less than 60 nm are able to aggregate fibronectin and albumin, which play an important role in cell adhesion.¹⁷² Therefore, the physical protrusion of the nanoscale structure facilitates antimicrobial resistance and the improvement of all cellular functions. It is the basis for solving the difficulties of implant osseointegration in a bacterial environment.

Osteogenesis and antibacterial. In a further development of the balance between antimicrobial/antifouling and promotion of cell adhesion, implant surfaces began to be screened for protein adhesion and cell membrane phospholipid affinity. Amphipathic ions were able to improve antifouling properties by reducing the adsorption of bovine serum albumin and fibrinogen. At the same time, it increases the affinity of cell membrane phosphorylcholine to promote the adhesion and proliferation of osteoblasts. It even promotes osteogenic differentiation because the phosphate group stimulates osteogenic signalling.¹⁷³ Amphoteric polymer coatings carrying positive and negative charges have better antimicrobial effects and osseointegration due to a stronger hydration layer and electrolyte affinity.^{174,175} Chitosan is rapidly developing in antimicrobial coatings due to its favourable affinity for amphoteric ions. Combining the advantages of nanostructures on 3D-printed titanium surfaces, the antimicrobial coating of quaternized chitosan significantly inhibits infection and promotes wound healing.¹⁷⁶ Functionalized chitosan resists fungal adhesion and bacterial adhesion by increasing positive charges, inhibiting non-nutritive fatty acid growth, transforming into natural antibiotics, and incorporating silver nanoparticles.^{176–179} However, due to the rapid absorption and metabolism of chitosan in the organism, the timeliness of its biological effects will also need to be addressed. The functionalisation of chitosan will become more and more sophisticated in the future, but the complexity and catabolism of coupling materials such as metals, ions, nucleic acids or peptides will also be an issue. How to simplify the complexity will become a major challenge.

From antibacterial to anti-inflammatory. Advanced mechanical modifications and coating technologies on implant surfaces have contributed significantly to the promotion of osseointegration and antimicrobial activity, especially with hydroxyapatite, calcium, silicon, and strontium coatings for osseointegration and silver, zinc, and copper for the maintenance of antimicrobial activity.^{180–183} Hydroxyapatite coatings are even more systematically involved in bone immunomodulation, promoting bone formation and angiogenesis as well as the ability to modulate macrophage immune responses.¹⁸⁴ However, the above modifications, such as mechanical, physical or chemical, are not efficient compared to the biomodification by direct loading of proteins, although biomodification also faces problems such as coating peeling, high cost of coating preservation, and limited clinical use.

Antibacterial. Tissue delivery of growth factors reprograms local tissue cells and improves the bone microenvironment,

which is not conducive to bone regeneration. Sustained-release antibiotic delivery systems, antimicrobial enzymes or chitosan polymer coatings further enhance the biocompatibility of the material while maintaining antimicrobial efficiency.^{185–187} The tetra-armed poly(ethylene glycol) hydrogel significantly prevents biofilm formation by non-specific adsorption of proteins, bacteria and platelets. With the co-deposition of plant polyphenols and/or other components, it can also significantly improve antimicrobial properties.¹⁸⁸ Ti–Ag–Cu and Mg–Ag–Cu nanoparticle coatings significantly reduced the adhesion of *Staphylococcus aureus*, *Staphylococcus epidermidis*, and *Escherichia coli* with little effect on cell viability.¹⁸⁹ Slow-release basic fibroblast growth factor (bFGF) and bone morphogenetic protein-2 (BMP-2) core/shell fibrous scaffolds induced M2 transformation of macrophages, which effectively promoted angiogenesis and osteogenesis of periodontal membrane stem cells (PDLSCs).¹⁹⁰ However, there is still a gap between the desired results under laboratory conditions and the clinical situation. The stability and reliability of this highly bioselective for adhesion and manipulation of osteoimmune deserves to be validated in further clinical trials.

Anti-inflammatory. In addition to the management of pathogenic bacteria, however, the regulation of inflammation requires direct intervention on macrophages, which play a decisive role in disease progression. Therefore, researchers designed a macrophage temporally sequential responsive coating. A photosensitive coating that responds to yellow light to produce antimicrobial properties and near-infrared light to produce a photothermal effect to promote osteogenic differentiation holds great promise for the treatment of peri-implantitis.¹⁹¹ The coating promoted macrophage secretion of factors contributing to osteogenic differentiation when the implant was initially placed, and promoted inflammatory macrophage apoptosis after bone maturation, significantly enhancing osseointegration.¹⁹² This gives hope for treatment in the clinic to improve the bone microenvironment through autoimmune modulation.

Osteoimmunity. Various coating technologies are also being explored for the possibility of modulating osteoimmunity. Hydrophilic nanostructured titanium coatings with surface sandblasting and acid etching (SLA) can remodel macrophage homeostasis to reduce the inflammatory response in type 2 diabetes and promote the M2 macrophage function to enhance bone healing.¹⁹³ Electrostatically spun nanofiber coatings of poly(lactic-co-glycolic acid) (PLGA)-loaded aspirin (ASA) promoted cellular osteogenic differentiation and inhibited M1 polarization as well as RANKL-induced osteoclast differentiation. *In vitro* experiments have even demonstrated a sustained release effect for up to 60 days and the inhibition of titanium particle-induced peri-implant osteolysis.¹⁹⁴ A strategy for functionalizing titanium surfaces has been developed, which involves the integration of mesoporous polydopamine (PDA) nanoparticles, a donor of nitric oxide (NO) called sodium nitroprusside (SNP), and an osteogenic growth peptide (OGP).

This approach combines resistance to drug-resistant bacteria with the modulation of the bone immune microenvironment to promote osteogenesis in MSCs and anti-inflammatory effects in RAW264.7 cells through multiple paracrine signaling pathways.¹⁹⁵ The above studies have demonstrated a variety of ways to modulate osteoimmune, with few comparisons of the differences in efficacy between them. More research studies are needed to model the process of innate osteoimmune, compare the various approaches and explore the most beneficial regimen for osseointegration in the clinic.

From anti-inflammatory to bone remodeling. The above study achieves the dual role of promoting osteogenesis and modulating inflammation, which facilitates the osseointegration of implants in inflammatory and other disorders. In the early stage of osseointegration, it is not only necessary to ensure the appropriate functioning of osteogenic differentiation, but also to inhibit osteoclastic activity. Silicon (Si) substitutes not only promote osteogenic induction of BMSCs but also reduce osteoclast production. The preparation of Si-substituted nanostructured hydroxyapatite-coated titanium implants was able to effectively inhibit inflammation-induced osteoclastic hyperostosis under diabetes, exhibiting optimal osseointegration efficiency.¹⁹⁶ The preparation of nanostructured akermanite-coated titanium implants can effectively inhibit osteoclastic hyperostosis manifested by the imbalance of bone homeostasis in osteoporosis and achieve bone regenerative healing in osteoporosis.¹⁹⁷ The metal-polyphenol coating containing magnesium ions demonstrated a synergistic effect of osteoinductive metal ions (Mg^{2+}) and polyphenols (EGCG) that significantly inhibited osteoclast maturation and enhanced osteoblast differentiation, favoring osseointegration of titanium implants on rabbits.¹⁹⁸ After being stimulated by near-infrared light, the surface of black TiO₂ nanotubes immobilized with IL-4/polydopamine released IL-4, which helped in reducing inflammation, inhibiting osteoclast differentiation and function, and enabling optimal osseointegration over a period of four weeks.¹⁹⁹ These methods ensure initial osseointegration of the implant, but lack the distant promotion of dynamic reconstruction of the peri-implant bone tissue.

As the alveolar bone undergoes remodelling, the restructuring of the peri-implant osseointegration continues in concert with osteogenesis and osteoclastogenesis. Active coatings are available that focus on inducing both osteoblasts and osteoclasts simultaneously. This helps to obtain the role of osteoclast metabolic factors in re-inducing osteogenesis and osteolysis. This, in turn, maintains and improves the structural strength of bone tissues.²⁰⁰ Chlorine-substituted hydroxyapatite/polydopamine composite coatings promote osteoclast and osteoblast induction through the eosinophilic nature of the former and the adhesive nature of the latter, respectively.²⁰¹ However, no animal studies have been performed to demonstrate this. Coatings of miR-21 nanocapsules on titanium can promote the development of both osteoblasts and osteoclasts, leading to faster bone remodeling and maturation. This process significantly increases the strength of osseointegration for implants.²⁰² However, there is a lack of sufficient basic and

animal studies on temporal sequential modulation of osteogenic and osteoclastic activities. Future surface modifications that can be applied clinically may need to direct osteogenic hyperactivity during the early stages of osseointegration, osteoclastic enhancement during remodelling, and bone homeostatic equilibrium during stabilization.

3.3. Extracellular vesicles

Due to safety concerns, stem cell therapy with immunomodulation and multidirectional functional differentiation is difficult to standardize for clinical applications. Extracellular vehicles (EVs) are critical paracrine components of stem cells that regulate the extracellular microenvironment.

EVs of MSCs originating from the endoderm. ADSC therapy facilitated inflammatory clearance and tissue regeneration after mechanical debridement of periodontitis but was less effective than ADSC-derived EVs.²⁰³ BMSC-derived EVs were found to promote human periodontal cell migration, proliferation, and osteogenic differentiation (hPDLCS). Additionally, these EVs were observed to significantly inhibit the osteoclastic differentiation of inflammatory infiltrates in areas of periodontitis bone defects under nanocomposite hydrogel loading, thus effectively slowing down the advancement of periodontal inflammation and immune damage.²⁰⁴ The use of dental pulp stem cell (DPSC)-derived EVs combined with the chitosan hydrogel helped in improving periodontal inflammatory osteolysis. This treatment worked by inhibiting proinflammatory development and promoting osteogenesis, which was linked to the presence of miR-1246.²⁰⁵ In addition to the mobilization of anti-inflammatory polarization of mononuclear macrophages, the modulation of the immune microenvironment also involves the suppression of T cells through gingival mesenchymal stem cell (GMSC)-derived EVs and the induction of Treg generation. This indirectly reverses the immune inflammatory environment and greatly enhances the regeneration of damaged periodontal tissues.²⁰⁶ Inflammation-stimulated stem cells seem to lean toward anti-inflammatory modulation. For example, under inflammatory conditions, dental follicle stem cell (DFSC)-derived EVs function as ROS-eliminating antioxidants, decreasing the RANKL/OPG ratio of PDLSCs and increasing the M2 phenotype polarization of macrophages *via* inhibition of JNK signaling and activation of ERK signaling, respectively.²⁰⁷ Injectable delivery platforms of GMSC-EVs or DFSC-EVs demonstrated healing effects on inflammatory periodontal osteolysis in animals due to the sustained release of EVs.^{206,207} As can be seen, EVs of MSCs are powerful enough to use osteoimmune to regulate the balance between osteogenesis and osteolysis. Even after inflammatory stimulation, these EVs demonstrated osteointegration-promoting effects. Further clinical studies are still needed in the future to verify the significant promotion of osteointegration by EVs of MSCs.

EVs of immune cells originating from the yolk sac. Yolk sac-derived immune cell EVs modulate osteoimmune interactions, balancing inflammation and maintaining bone homeostasis. IL10, enriched in M2-EVs, is the messenger of osteogenesis promotion and osteoclastic inhibition, mediating the dual

treatment of inflammation and osteolysis in periodontitis mice.²⁰⁸ Interestingly, inflammation-stimulated osteoclast-derived exosomes (iOC-Exos) have a negative feedback role in promoting osteogenic activity. The iOC-Exos targeted ephrinA2/EphA2 in the osteoblast membrane and then delivered the lncRNA LIOCE to stabilize the osteogenic transcription factor osterix to promote bone formation.²⁰⁹ In addition to stronger immunomodulatory effects of EVs of immune cells, they are also very effective in promoting osteogenic differentiation.

EVs of neuronal cells originating from the ectoderm. Neuralization has the potential to balance multisystem homeostasis in the regulation of the bone immune microenvironment, as hydrogel-encapsulated Schwann cell-derived exosomes (SC-Exos) promoted anti-inflammation, angiogenesis, and osteogenesis *in vitro*.²¹⁰ More future studies on EVs of neuronal cells in bone homeostasis regulation are needed to explore their commonalities and specificities.

EVs originating from bacteria and plants. Bacterial-derived EVs also hold great promise in the immunomodulatory treatment of inflammatory osteolysis. A vaccine composed of Pg-derived EVs (Pg-EVs) combined with a TLR agonist produced Pg-specific antibodies in mice, which safely yet stably maintained the suppressive viability of Pg in mice.²¹¹ Bacterial-derived EVs can also act as antibiotic carriers to kill pathogenic bacteria and eliminate the infection.²¹² Plant-derived exosomes, such as ginger exosome-like nanoparticles (GELNs), can target Pg for killing and have potential therapeutic promise against periodontal or peri-implant inflammatory osteolysis.²¹³ These EVs have some antimicrobial effects, but there is still a lack of exploration of their biomodulatory effects in animals and humans.

4. Discussion

This review provides a comprehensive overview of the intricate interplay between cells, proteins, RNA, epigenetic modifications, and podosomes in regulating the osteoimmune microenvironment during inflammatory osteolysis. This review summarizes recent advancements in promoting the osteogenic differentiation of osteogenic progenitor cells and preventing inflammatory polarization and osteolytic differentiation of immune cells to enhance peri-implant osseointegration as well as prevent inflammatory bone loss. While identifying key therapeutic targets is challenging owing to the complex and ever-changing nature of the microenvironment in inflammatory osteolysis, recent research has yielded promising results. For example, Withaferin-A has been found to induce M1 macrophages to release proinflammatory cytokines and oxidative stress markers, reverse the M1/M2 cell ratio, and encourage the differentiation of M1 macrophages into M2 macrophages.²¹⁴ Moreover, M2 exosomes derived from M2-type macrophages, as well as IL10 and betamethasone sodium phosphate, have been shown to promote the repolarization of M1 to M2 macrophages and significantly reduce inflammatory expression in mice with rheumatoid arthritis.²¹⁵ Future studies

could further simplify the process of bone immunomodulation and more efficiently reverse poor osteogenesis in inflammatory environments.

To promote pro-inflammation in localized regions during bone remodeling and anti-inflammation in localized regions during bone neogenesis, future treatments must account for the spatiotemporal-dependent modulation of inflammatory properties. Moreover, the spatial distribution of cells is crucial in directing cellular behavior and maintaining tissue homeostasis, which likewise facilitates the regulation of the bone immune microenvironment. Recent research has found that Tai Chi-shaped multicellular patterns of MSCs and macrophages in a 2:1 numerical ratio play a more significant role in mediating paracrine inhibition of inflammation and regulating osteogenic differentiation than star- and interlacing-shaped multicellular patterns.²¹⁶ This finding presents a new approach to implant surface modification.

In addition to direct osteoimmune modulation, researchers have explored immunomodulation-related bone microbiology, such as probiotics, which have been found to have anti-bone loss effects by increasing the Treg-Th17 cell ratio and modulating inflammation-related factors.²¹⁷ This technique may prove to be a powerful tool for regulating bone microenvironment homeostasis in the future.

Current research has yet to uncover the specific bone immune mechanisms underlying inflammatory osteolysis around implants. The academic community has not reached a consensus on the long-term stable immune inflammatory response between implants and surrounding soft and hard tissues. Similarly, apart from bacterial factors, there is also no consensus on the pathogenesis of periprosthetic inflammation, adding uncertainty to the treatment of inflammatory osteolysis around implants. This review outlines the targets for bone immune mechanisms, including cells, proteins, epigenetic modifications, RNA, and podosomes, and introduces the development prospects of electrobioactive materials, implant surface modification, and extracellular vesicles in the treatment of periprosthetic inflammation. However, there are still many biomimetic methods for regulating bone immunity that warrant further research. Similarly, the output voltage of electrobioactive materials, the long-term stability and safety of materials, the specificity of targeted drugs, and issues such as implant surface delamination and cost are also worthy of further investigation.

Overall, recent advances in understanding the complex mechanisms underlying the osteoimmune microenvironment offer exciting opportunities for developing new therapeutic approaches to prevent and treat inflammatory bone loss. The development of the three osteoimmunotherapeutic approaches to peri-implant inflammatory osteolysis described above is not independent and should perhaps cross over into each other in future clinical use. In the early intervention of osteoimmunity at the time of implant placement, bionic treatment of the implant surface can be combined with electrobiomaterials in order to achieve temporal and spatial specificity of osteoimmunomodulation in the microenvironment of inflammatory

osteolysis. At different stages of disease progression, treatment of EVs around diseased tissues with inflammatory osteolysis may enable *in vitro* modulation of osteoimmunotherapy for peri-implantitis. Future clinical use that combines the advantages of the above methods will certainly be rewarding in the treatment of inflammatory osteolysis around implants.

5. Conclusions

There are many potential therapeutic targets underlying cells, proteins, epigenetic modifications, RNA, and podosomes in the osteoimmune mechanisms of peri-implant inflammatory osteolysis. However, bioengineering treatments such as electro-biomaterials, implant surface modifications, and EVs have not fully developed specific targets for harnessing osteoimmune to treat peri-implant inflammatory osteolysis. Therefore, the integration of bioengineering treatment approaches and immune targets is the direction for future research.
