Pt-free MoS₂ co-catalyst enables record photocurrent density in Sb₂Se₃ photocathodes for highly efficient solar hydrogen production†

Munir Ahmad,^a Anadil Gul,^b Hafiz Sartaj Aziz,^a Tahir Imran,^a Muhammad Ishaq,^a Muhammad Abbas,^a Zhenghua Su^a and Shuo Chen^{*a}

Antimony selenide (Sb₂Se₃) emerges as a potential light-absorbing material for thin film photovoltaics and photoelectrochemical (PEC) water-splitting devices, due to its earth-abundant constituents and excellent photoelectric properties. However, losses caused by corrosion and sluggish charge transfer at the semiconductor/electrolyte interface require a co-catalyst to enhance these kinetic factors. In this study, MoS₂ is employed as a cost-effective, noble-metal-free catalyst to enhance the photocurrent density (J_{ph}), half-cell solar-to-hydrogen (HC-STH) conversion efficiency and stability of Sb₂Se₃-based photocathodes. Optimized thermodynamic/kinetic physical vapor deposition of MoS₂ substantially improves PEC performance, resulting champion Mo/Sb₂Se₃/CdS/MoS₂ photocathode that achieves a record J_{ph} of 31.03 mA cm⁻² at 0 V_{RHE} and the highest HC-STH efficiency of 3.08%, along with stability for over 5 hours in an acidic (pH 1) buffer solution. It is systematically revealed that MoS₂ reduces the photo-corrosion effect, decreases electron-hole recombination, and provides a significant increase in charge transfer efficiency at the semiconductor/electrolyte interface. This work highlights the potential of cost-effective, high-performance Sb₂Se₃-based photocathodes in advancing efficient PEC devices for solar hydrogen production.

1. Introduction

Hydrogen production by solar-driven water splitting in photoelectrochemical (PEC) devices is one of the most attractive strategies to convert clean and abundant radiation into non-polluting and storable chemical fuels.¹ Hydrogen energy is a carbon-free fuel that can be used in various industries, transportation, and heating applications. Currently, burning fossil fuels produces the majority of hydrogen, which leads to serious carbon emission problems.² Production of green hydrogen energy through sunlight harvesting is a highly efficient approach for overcoming worldwide environmental problems and energy shortages; however, it remains challenging.³ Recently, different research groups have focused on introducing new photocatalysts or advanced methods to produce hydrogen energy through water splitting. Among these

technologies, PEC solar water splitting is a clean, sustainable, and cost-effective, technique to produce hydrogen from solar irradiation.⁴ Some well-studied oxides, for example, CuFeO₂⁵ and Cu₂O,⁶ and different chalcogenides like CuInS₂,⁷ CuGaSe₂,⁸ and CuIn_{1-x}Ga_xSe₂ (ref. 9 and 10) as well as newly emerging materials like Cu₂ZnSn(S,Se)₄,² Cu₂BaSn(S,Se)₄¹¹ and Sb₂Se₃¹²⁻¹⁴ are studied as photocathode materials.

Among the materials for hydrogen production, Sb₂Se₃ has emerged as an excellent light-absorbing material for PEC applications because of its earth-abundant elements, low-cost, eco-friendly, high absorption coefficient (>10⁵ cm⁻¹), suitable bandgap (~1.2 eV), and remarkable photoelectric properties. Additionally, Sb₂Se₃ exhibits intrinsic stability in neutral and acidic electrolytes, with negligible self-reduction or photo-corrosion, making it a suitable material for efficient PEC photocathodes.¹⁵ Despite these advantages, Sb₂Se₃-based photocathodes face many challenges such as surface corrosion caused by multiple functional layers, electron-hole non-radiative recombination caused by defects, and sluggish charge transfer at the semiconductor/electrolyte interface, which limit their PEC efficiency and long-term stability. To address these challenges, employing a suitable co-catalyst on the photocathode surface is very important. Noble metals like platinum (Pt) have been widely used as co-catalysts in Sb₂Se₃-based photocathodes, but their high cost and rare availability limit their commercial applications.^{16,17} Hence, the search for

cost-effective and non-toxic alternative co-catalysts is highly desirable for developing efficient Sb_2Se_3 -based photocathodes.

Recently, the development of co-catalysts like metal alloys, carbides, phosphides, nitrides, borides, and chalcogenides for the representative hydrogen evolution reaction (HER) has made significant progress.^{18,19} Among them, molybdenum sulfide (MoS_2) has gained attention as a promising noble-metal-free co-catalyst. As a transition metal dichalcogenide (TMD), MoS_2 possesses a suitable 2D layered structure, excellent chemical stability, and favorable band alignment for inducing the HER.^{20,21} Additionally, amorphous MoS_2 has a high concentration of active sites at the edge layers, which enhances its electrocatalytic activity as compared to the crystalline form.²² A solution-based approach to synthesize MoS_2 (crystalline/amorphous) has been used in different photocathodes (e.g., Cu_2O , $\text{Cu}_2\text{ZnSnS}_4$, and Sb_2Se_3).^{23,24} Actually, it still encounters challenges in terms of scalability, thickness uniformity, and composition variability.²⁴ In contrast, physical vapor deposition (PVD) techniques, such as sputtering, provide a suitable preparation method for producing uniform, large-scale, and stable MoS_2 thin film co-catalysts; however, this approach remains underexplored.²⁵

This work started the preparation of eco-friendly Sb_2Se_3 light-harvesting films with favorable growth orientation and large crystal grains through an efficient combination reaction involving pre-sputtered and post-selenized Sb metallic precursors. After CdS buffer layer deposition, the binary compound MoS_2 was sputtered as a co-catalyst instead of using noble-metal Pt, with a focus on MoS_2 co-catalyst thickness engineering to enhance both light-harvesting efficiency and HER activity. In short, the introduction of optimized MoS_2 could significantly alleviate the photo-corrosion effect, suppress charge carrier recombination loss, and reduce the charge transfer resistance at the semiconductor/electrolyte interface. Moreover, the MoS_2 incorporation contributed to a favorable surface wettability with more reaction sites and favorable surface band bending with accelerated photoelectron transfer characteristics. As a result, the champion MoS_2 -modified Pt-free Sb_2Se_3 photocathode exhibited a record photocurrent density (J_{ph}) of 31.03 mA cm^{-2} at 0 V versus the reversible hydrogen electrode (RHE, V_{RHE}), and the highest half-cell solar-to-hydrogen (HC-STH) conversion efficiency of 3.08% in a pH 1 acid buffer solution. Furthermore, the device exhibited a significant improvement in long-term stability as compared to its Pt-involved counterpart. This work highlights the potential of PVD-processed MoS_2 as a cost-effective and highly-efficient co-catalyst, advancing the development of efficient and stable Sb_2Se_3 -based photocathodes for solar hydrogen production.

2. Experimental section

2.1. Preparation of $\text{Sb}_2\text{Se}_3/\text{CdS}/\text{MoS}_2$ photocathodes

The Sb_2Se_3 light-absorbing layer and CdS buffer layer were sequentially deposited on a Mo-coated soda lime glass substrate according to our previously reported work.²⁶ After the deposition of Sb_2Se_3 and CdS, the MoS_2 layer with different thicknesses ranging from 20 to 40 nm was deposited as a co-catalyst

by RF (radio frequency) magnetron sputtering using a MoS_2 target. It was carried out with a 50 W sputtering power, an Ar gas flow of 50 sccm, and a working pressure of 2 Pa. The MoS_2 layer thickness was controlled by sputtering deposition times of 400 s, 600 s, and 800 s, yielding 20, 30, and 40 nm MoS_2 layers based on a 0.05 nm s^{-1} deposition rate, and the corresponding samples were labelled as M-20, M-30, and M-40 respectively. Finally, the Mo layer was exposed at the thin film edge to achieve a conductive back contact, and Ag colloids were deposited on its surface by thermal evaporation. The schematic of the synthesis process of glass/Mo/ Sb_2Se_3 /CdS/ MoS_2 photocathode is shown in Fig. S1 (ESI).†

2.2. Characterization

The crystallinity of Sb_2Se_3 -based photocathodes was studied by X-ray diffraction (XRD) using an Ultima-IV diffractometer with Cu K_α radiation. The morphologies of the surface, cross-section, and structure were acquired using a scanning electron microscope (SEM, Zeiss SUPRA 55) and the corresponding elemental composition was studied by using an energy dispersive spectroscope (EDS, BRUKER QUANTAX 200). The valence states of the involved elements were studied using X-ray photoelectron spectroscopy (XPS, Thermo Scientific ESCALAB 250Xi). *In situ* sputter etching was performed using a 10 kV Gas Cluster Ion Beam (GCIB) with a $6 \times 6 \text{ mm}^2$ surface treatment area during the XPS measurement. Atomic force microscopy (AFM) operated, *via* NT-MDT spectrum instruments in semi-contact mode, was used for the investigation of thin film morphology and surface roughness. Surface potential and topography characterization were further analyzed through a Kelvin probe force microscope (KPFM, Bruker Dimension ICON). Raman spectroscopy (Renishaw, InVia) was used for studying bonding information. PEC performance characterization was performed with an electrochemical workstation (CHI660e) under a three-electrode configuration, *i.e.*, Ag/AgCl electrode as the reference electrode, Pt-wire as the counter electrode, and the as-fabricated photocathode as the working electrode. All tests were performed in acid electrolyte under simulated sunlight illumination (AM 1.5G) at a calibrated light intensity of 100 mW cm^{-2} . Photoelectrochemical impedance spectroscopy (PEIS) was performed under simulated sunlight illumination in a 10^{-1} to 10^2 kHz frequency range at 0 V_{RHE} . Mott-Schottky (M-S) experiments were performed in the dark using a 30 mV AC amplitude, scanning voltage between -0.5 and 0.1 V and a frequency of 10^4 Hz .

3. Results and discussion

Mo/ Sb_2Se_3 /CdS/ MoS_2 thin-film photocathodes with different MoS_2 co-catalyst loading amounts (*i.e.*, 20 nm, 30 nm, and 40 nm) were prepared and studied; the corresponding devices were labelled as M-20, M-30, and M-40, respectively. Their PEC performance was measured using a classical 3-electrode PEC workstation, as shown in Fig. 1a. Upon light illumination, continuous visible hydrogen bubbles were observed on the photocathode surface, which migrated toward the acidic

Fig. 1 (a) Schematic diagram of a typical three-electrode PEC measurement system. (b) A picture of hydrogen bubbles originating from the surface of the photocathode and moving towards the electrolyte; (inset) photograph of a typical Sb_2Se_3 photocathode. J - V curves of the photocathodes under dark conditions and chopped sunlight illumination (c), and under dark conditions and continuous sunlight illumination (d). (e) The obtained HC-STH conversion efficiencies. (f and g) A comparison of our work with some state-of-the-art chalcogenide-based photocathodes. Statistical plots of M-20, M-30, and M-40 photocathodes, i.e., (h) J_{ph} , (i) V_{on} , and (j) HC-STH conversion efficiencies.

electrolyte (i.e., 0.5 M H_2SO_4), indicating the efficient HER through water splitting (Fig. 1b). The as-prepared Sb_2Se_3 photocathodes of area $2 \times 2 \text{ cm}^2$ were quasi-homogenous, as shown in Fig. 1b (inset), suggesting great potential in scalable applications. Before performing PEC measurements, a defined active area of 0.95 cm^2 was exposed using a water-resistant, light-resistant glue to ensure accurate and reproducible performance evaluation. Generally, the thickness of both the light-absorbing layer (Sb_2Se_3) and co-catalysts (MoS_2) is very important for balancing charge carrier generation and HER activity. The current density–potential (J - V) curves of the M-20, M-30, and M-40 photocathodes under chopped light illumination and continuous light illumination are depicted in Fig. 1c and d, respectively. The M-20 photocathode with a 20 nm MoS_2 layer exhibited relatively low PEC performance, with a low J_{ph} of $\sim 21.93 \text{ mA cm}^{-2}$ at $0 V_{\text{RHE}}$. Moreover, its unsatisfactory HC-STH conversion efficiency of 2.22% was measured using the following equation:²

$$\text{HC-STH} (\%) = J_{\text{ph}} \times (V_{\text{RHE}} - V_{\text{H}^+/\text{H}_2}) / P_{\text{SUN}} \times 100\% \quad (1)$$

where J_{ph} is the photocurrent density at an applied potential of V_{RHE} , $V_{\text{H}^+/\text{H}_2}$ represents the equilibrium redox potential for hydrogen ($0 V_{\text{RHE}}$), and P_{SUN} denotes the sunlight intensity, set at 100 mW cm^{-2} . This low PEC performance can be attributed to insufficient active sites, poor protection against photo-corrosion and higher recombination rates. When the MoS_2 layer thickness was increased to 30 nm (M-30), an obvious increase in J_{ph} was observed, reaching $\sim 31.03 \text{ mA cm}^{-2}$ (Fig. 1c), along with an impressive HC-STH conversion efficiency exceeding 3%. This optimized MoS_2 could provide ideal surface coverage with more active sites and photoelectron transport pathways, while decreasing surface defects and recombination centers. It effectively achieved a balance between light absorption and catalytic activity, allowing efficient solar water splitting and hydrogen production. However, further increasing the MoS_2 layer thickness to 40 nm (M-40) led to

Table 1 Summary of the PEC performances of different photocathodes using MoS_x compound as a co-catalyst

Photoelectrode	HER co-catalyst	Buffer solution	J_{ph} (mA cm ⁻²)	V_{on} (V_{RHE})	HC-STH (%)	Stability (time, remain)	Reference
Sb ₂ Se ₃	MoS ₂	pH 1	31.03	0.43	3.08	5 h, 90%	This work
Sb ₂ Se ₃	MoS _x	pH 1	27	0.40	2.6	1.5 h, 93%	28
Sb ₂ Se ₃	MoS _x	pH 0	16	0.25	N/A	2 h, 70%	29
Sb ₂ Se ₃	MoS _x	pH 1	4.8	0.15	N/A	N/A	30
Sb ₂ Se ₃	MoS ₂	pH 6.5	10	0.5	N/A	N/A	20
CZTS	MoS _x	pH 3	18	0.60	3.0	10 h, 70%	27
Si	MoS ₂	pH 0	17.6	0.25	N/A	3 h, 78%	31
GaP	MoS _x	pH 0	6.4	0.71	1.50	N/A	32
p-Si	MoS ₂	pH 1	42.3	0.72	0.64	15 h	33
n ⁺ n p ⁺ -Si	MoS ₂	pH 1	36.34	0.5	5.5	10 h	34
InP	MoS ₃	pH 0	22	0.6	6.4	1 h, 90%	35

a decrease in J_{ph} (~ 26.97 mA cm⁻²) and HC-STH efficiency (2.34%). This indicates that beyond a certain thickness, the MoS₂ layer impeded light penetration into the Sb₂Se₃ absorber layer to generate charge carriers due to serious parasitic light absorption losses.²⁷ To further validate the optimization, additional samples with 25 nm (M-25) and 35 nm (M-35) MoS₂ thicknesses were investigated, both of which exhibited inferior PEC performance compared to M-30, with lower J_{ph} (~ 25.84 mA cm⁻² and 29.21 mA cm⁻²) and HC-STH efficiencies (2.60% and 2.75%) respectively (Fig. S2a and b†). These results further confirm that 30 nm represents the optimal MoS₂ thickness for maximizing PEC performance in our Mo/Sb₂Se₃/CdS/MoS₂ photocathode system. Additionally, another indicator of onset potential (V_{on}), usually defined as the potential at which the steep J - V curves start, herein, was precisely measured by extrapolating the J - V curves in the quickly increasing regions (Fig. S3†). It is very important to mention that the obtained J_{ph} (~ 31.03 mA cm⁻²) and V_{on} (~ 0.43 V_{RHE}) values belonging to the champion M-30 photocathode are obviously higher than those of previously reported MoS₂-coated Sb₂Se₃-based photocathodes (Fig. 1f, g and Table 1). They also provide a comparative analysis of the PEC performance against previously reported state-of-the-art MoS₂ co-catalyst-based Si, InP, GaP, and CZTS photocathodes; our device demonstrates comparable performance, especially with a higher J_{ph} . Finally, the statistical distributions of different performance parameters are shown in Fig. 1h-j, presenting synchronous variation with key MoS₂ thickness, confirming satisfactory reproducibility for efficient scalable solar hydrogen evolution applications.

A detailed morphological and structural investigation was first carried out to validate the quality of the Sb₂Se₃ light-absorbing thin film, the interface modification *via* MoS₂ as a co-catalyst, and its impact on PEC performance of the device. The XRD patterns of the pure Sb₂Se₃ and Sb₂Se₃/CdS/MoS₂ thin films are presented in Fig. 2a. The high purity and crystallinity of the as-deposited Sb₂Se₃ films are confirmed by the presence of four major diffraction peaks, corresponding to the (211), (221), (321), and (002) planes, consistent with the standard Sb₂Se₃ (JCPDS Card No. 15-0861). These distinct peaks suggest the formation of a highly crystalline light-absorbing layer, which is crucial for minimizing defect states and optimizing

charge carrier mobility within the film. After deposition of CdS and MoS₂, two additional peaks appear at 24.97° and 58.9° corresponding to the (111) plane of CdS and (110) plane of MoS₂, according to JCPDS Card No. 41-1049 and JCPDS Card No. 37-1492, respectively. The peak observed for MoS₂ is assigned to pure MoS₂ highlighted in Fig. S4a,† while its compact granular structure can also be observed from the SEM image of MoS₂ in Fig. S4d†. The (111) plane of CdS, known for its optimal electron transport properties, combined with the catalytic (110) plane of MoS₂, suggests, improved charge transfer and catalytic activity at the semiconductor/electrolyte interface, likely contributing to enhanced PEC performance observed in the Sb₂Se₃/CdS/MoS₂ photocathode.³⁶ The obtained results were further confirmed by analyzing the texture coefficient (TC) to examine the preferred orientation in Sb₂Se₃ and Sb₂Se₃/CdS/MoS₂ thin films, using the following equation:³⁷

$$\text{TC}(hkl) = \frac{I(hkl)}{I_0(hkl)} \frac{1}{N} \sum_{i=1}^N \frac{I(h_i k_i l_i)}{I_0(h_i k_i l_i)} \quad (2)$$

where N , $I(hkl)$, and $I_0(hkl)$ show the peak number utilised during calculations, the intensity of the measured diffraction, and the reported diffraction intensity (PDF card), respectively. Fig. 2b illustrates an overall increase in the TC of ($hk1$) planes, coupled with a decrease in the TC of the ($hk0$) planes after the deposition of CdS and MoS₂ layers on the Sb₂Se₃ thin film, suggesting a reorientation of the crystallographic structure of Sb₂Se₃ driven by the post-deposition processes. The improvement of the ($hk1$) planes is typically associated with optimal carrier transport and high charge mobility, resulting improved charge transfer pathways in the Sb₂Se₃/CdS/MoS₂ photocathode.³⁷ Fig. 2c presents the Raman spectra of pure Sb₂Se₃ and Sb₂Se₃/CdS/MoS₂ thin-film photocathodes. In the Sb₂Se₃ spectrum, the most prominent peak of Sb₂Se₃ phase around 190 cm⁻¹ is observed, which refers to the A_{2u} mode of the Sb-Sb bond, one of the most common vibrational modes in the Sb₂Se₃ phase. The additional peak around 210 cm⁻¹ corresponds to Sb-Se bond vibration within the Sb₂Se₃ unit. In the Sb₂Se₃/CdS/MoS₂ spectrum, an intense peak appears around 300 cm⁻¹ corresponding to the longitudinal optical mode of the

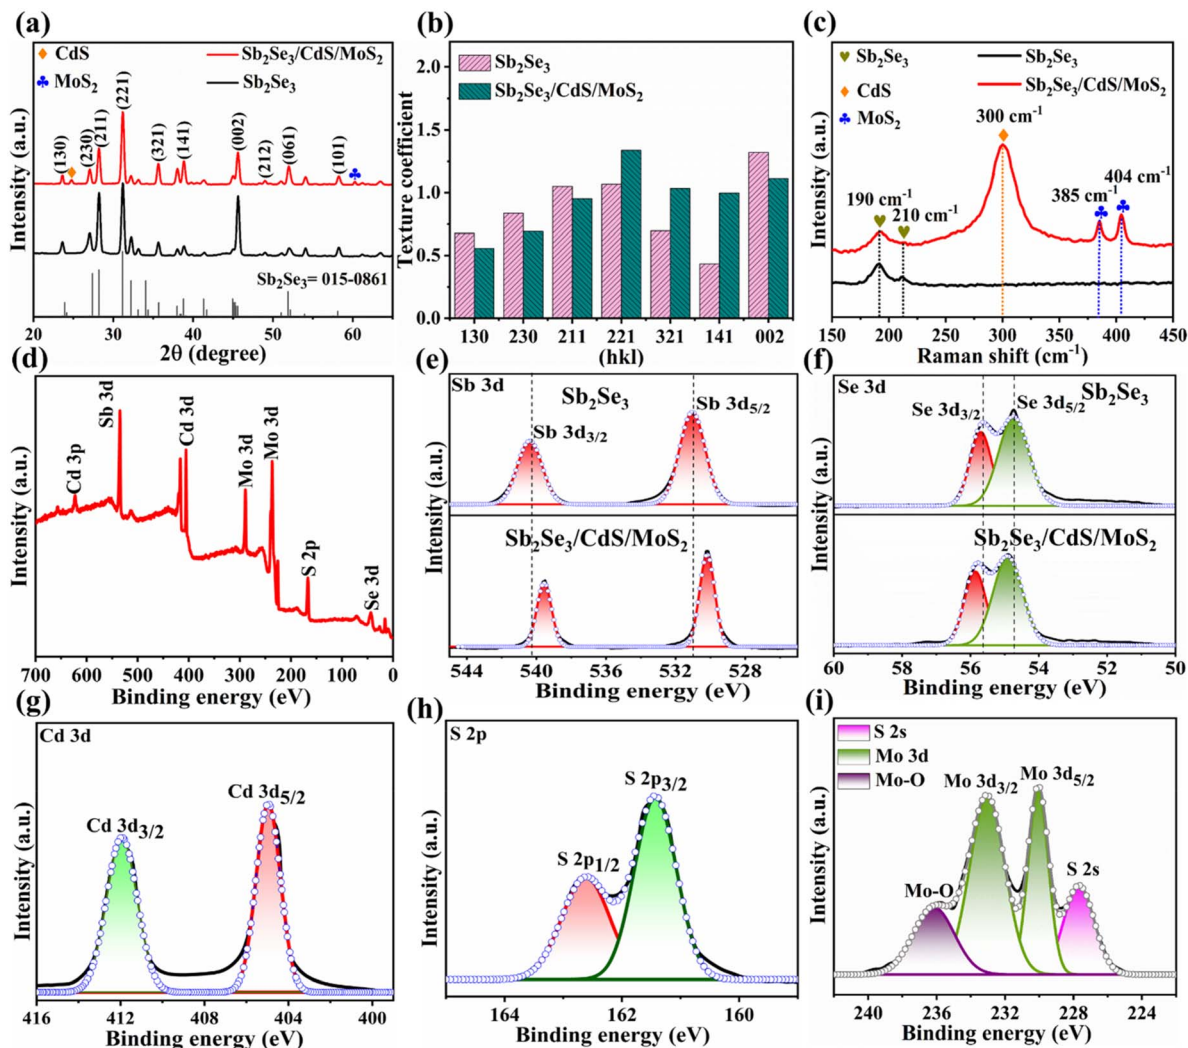

Fig. 2 (a) XRD, (b) texture coefficient of XRD peaks, and (c) Raman spectra of bare Sb_2Se_3 and $\text{Sb}_2\text{Se}_3/\text{CdS}/\text{MoS}_2$ samples. (d) XPS survey graph of $\text{Sb}_2\text{Se}_3/\text{CdS}/\text{MoS}_2$, the binding energy displacement of (e) Sb and (f) Se. XPS spectra for (g) Cd 3d, (h) S 2p, and (i) Mo 3d.

hexagonal CdS buffer layer. Moreover, two additional peaks at about 385 cm^{-1} and 405 cm^{-1} are observed, which correspond to the in-plane E_{2g} and out-plan A_{1g} modes of MoS_2 , respectively.³⁸ The presence of these characteristic peaks in Raman spectra of the pure as-deposited MoS_2 thin film (Fig. S4c†) confirms the successful deposition and integration of the crystalline MoS_2 layer within the $\text{Sb}_2\text{Se}_3/\text{CdS}/\text{MoS}_2$ photocathode via the PVD process. Importantly, its layered structure and beneficial crystallographic orientation might interact synergistically with the $\text{Sb}_2\text{Se}_3/\text{CdS}$ layers to reduce the photo-corrosion effect, and provide a substantial decrease in charge transfer resistance.³⁹

X-ray photoelectron spectroscopy (XPS) investigations were performed to better understand the chemical composition. Fig. 2d shows the XPS survey spectra of $\text{Sb}_2\text{Se}_3/\text{CdS}/\text{MoS}_2$. Fig. 2e demonstrates the Sb 3d spectra with binding energies b/w 525 and 545 eV for both bare Sb_2Se_3 and $\text{Sb}_2\text{Se}_3/\text{CdS}/\text{MoS}_2$. The separation between the peaks of Sb 3d doublet pairs was retained at 9.58 eV.⁴⁰ It was also confirmed from the Se spectra

shown in Fig. 2f, that two doublets of Se ($3d_{5/2}$ and $3d_{3/2}$), separated by 0.78 eV energy, showing the presence of Se^{2-} . Moreover, Fig. 2e reveals a prominent shift in the Sb 3d peak toward lower binding energy in the case of $\text{Sb}_2\text{Se}_3/\text{CdS}/\text{MoS}_2$. As an explanation, at the $\text{Sb}_2\text{Se}_3/\text{CdS}/\text{MoS}_2$ interface, the higher Fermi levels of n-type CdS and MoS_2 cause electron flow to p-type Sb_2Se_3 until equilibrium is reached, resulting in band bending, with Sb_2Se_3 bands shifting upward and the CdS/ MoS_2 bands bending downward, also confirming the favorable formation of the $\text{Sb}_2\text{Se}_3/\text{CdS}/\text{MoS}_2$ junction. Two notable peaks positioned at 412.2 eV and 405 eV (shown in Fig. 2g) are assigned to Cd $3d_{3/2}$ and $3d_{5/2}$ respectively. Fig. 2h shows two distinguished peaks located at 162.8 eV and 161.5 eV, which correspond to S $2p_{1/2}$ and S $2p_{3/2}$ respectively. The Mo 3d and S 2s core level regions, with binding energies ranging from 222 to 242 eV, are depicted in Fig. 2i. The Mo 3d doublet peaks demonstrating the presence of Mo^{4+} (Mo $3d_{5/2}$ and Mo $3d_{3/2}$) appear around 229 and 232 eV, respectively. These peaks are characteristic of the MoS_2 structure, confirming that Mo occurs

primarily in its active Mo^{4+} state, which is important for promoting efficient charge transfer and catalyzing the HER. Furthermore, the S 2s peak around 226 eV confirms the presence of sulfur (S^{2-}) in the MoS_2 layer.⁴¹ The Mo 3d third peak around 235 eV corresponding to the Mo^{6+} state of MoO_3 shows the presence of a Mo oxide state in MoS_2 . The presence of MoO_3 shows the oxidation of the MoS_2 layer, which may result from sulfur vacancies during deposition or exposure to air, where sulfur vacancies react with oxygen, or from interactions between Mo and the substrate surface.⁴²

Scanning electron microscopy (SEM) images show the surface morphologies of Sb_2Se_3 , $\text{Sb}_2\text{Se}_3/\text{CdS}$ and $\text{Sb}_2\text{Se}_3/\text{CdS}/\text{MoS}_2$ thin films depicted in Fig. 3a–c. Additionally, the corresponding energy dispersive spectroscopy (EDS) information is presented in Fig. S5a–c,[†] which supports the elemental composition. The smooth surface morphology of pristine

Sb_2Se_3 becomes rougher gradually after the deposition of the CdS and MoS_2 layers. This enhanced surface roughness indicates the successful deposition of CdS and MoS_2 layers and is predicted to have an impact on the photocathode's light absorption and charge carrier dynamics. The cross-sectional SEM images (Fig. 3d–f) confirm the compact deposition of all three layers. MoS_2 forms a conformal layer over the CdS-coated Sb_2Se_3 surface, potentially covering grain boundaries and interfaces without significantly altering the surface topography. This homogeneous distribution of MoS_2 is very important for enhancing charge separation and creating efficient electron transport pathways, thus enhancing PEC performance.²⁷ Wettability is an important parameter assessed by measuring the contact angle (CA) between solid and fluid surfaces and can be classified as completely wettable ($\text{CA} = 0^\circ$), hydrophobic or poorly wettable ($\text{CA} > 90^\circ$) and hydrophilic or partially wettable

Fig. 3 SEM micrographs of (a) Sb_2Se_3 , (b) $\text{Sb}_2\text{Se}_3/\text{CdS}$, and (c) $\text{Sb}_2\text{Se}_3/\text{CdS}/\text{MoS}_2$ samples. (d–f) The corresponding cross-sectional SEM images. (g–i) The measured CAs (using H_2SO_4 electrolyte droplets) of the samples, and (j–l) AFM images of the sample surfaces.

($CA < 90^\circ$).⁴⁰ The wettability of Sb_2Se_3 , Sb_2Se_3/CdS , and $Sb_2Se_3/CdS/MoS_2$ (M-30) samples was examined through CAs formed between the sample surfaces and H_2SO_4 electrolyte droplets. According to Fig. 3g–i, the Sb_2Se_3 , Sb_2Se_3/CdS , and $Sb_2Se_3/CdS/MoS_2$ (M-30) sample surfaces exhibit hydrophilic nature with CAs of 88.6° , 79.5° , and 69.8° , respectively. To further validate this, the CAs of 89.2° , 67.6° , and 56.3° for the same samples were also measured by using glycerol droplets which display similar trends as depicted in Fig. S7a–c.† Importantly, the M-30 sample depicts the minimum CA, demonstrating a significant enhancement in wettability after MoS_2 deposition. Additionally, the M-20 and M-40 samples display higher CA values of 76.9° and 72.2° (Fig. S6a and b)†, respectively, which are still lower than that of Sb_2Se_3/CdS but higher than that of the M-30 sample which suggests that the M-30 sample achieves optimal wettability among the other samples. This variation is closely related to changes in roughness, surface tension of liquids, free energy, and grain size of the solid surface. Such enhanced wettability improves the PEC performance of photocathodes by increasing the number of exposed reaction sites and enabling photoelectron transfer.²⁶ The roughness and surface morphologies of the corresponding Sb_2Se_3 , Sb_2Se_3/CdS , and $Sb_2Se_3/CdS/MoS_2$ thin films were studied using atomic force microscopy (AFM) (Fig. 3j–l). Additionally, 2D and 3D images of the pure MoS_2 thin film are shown in Fig. S9a and b.† The average root mean square (RMS) surface roughness value of Sb_2Se_3 is 105 nm, followed by

117 nm for Sb_2Se_3/CdS , and 154 nm for the $Sb_2Se_3/CdS/MoS_2$ (M-30) thin film surface. Notably, the M-20 and M-40 samples exhibit RMS roughness values of 129 nm and 146 nm, respectively (Fig. S8a and b)†, which are lower than that of the M-30 sample. This indicates that the M-30 sample has the most textured surface among the MoS_2 -coated samples, which may contribute to its higher PEC performance. Thus, it can be speculated that the improvement in wettability of $Sb_2Se_3/CdS/MoS_2$ might be result from the evolution of surface roughness, which matches well with the roughness-dependent wettability model presented by Wenzel, *i.e.*, the roughness will make a naturally hydrophilic surface more hydrophilic.⁴³

Kelvin probe force microscopy (KPFM) analysis was then performed; this advanced technique allowed us to study the topography and contact potential difference (V_{CPD}) across thin films, providing critical insights into their surface properties. Fig. 4a, e and i show the micrographs, and Fig. 4b, f, and j show the surface potential distributions for Sb_2Se_3 , Sb_2Se_3/CdS , and $Sb_2Se_3/CdS/MoS_2$ samples, respectively. The AFM images indicate that the surface morphology of the Sb_2Se_3 thin films remains consistent across different layer depositions, which correlates well with the top-view SEM micrographs (Fig. 3a–c). The pronounced contrast in CPD between grain interiors and boundaries indicates a strong intergranular carrier extraction, which facilitates efficient charge separation and carrier transport, contributing to enhanced PEC performance. The white

(c, g and k) The corresponding topography and potential line scans acquired from the white arrow lines. (d, h and l) Schematic of the energy band structure and CPD near the GBs, where “e⁻” represents electrons; “h⁺” represents holes.

arrow line scans, which show CPD variations for Sb_2Se_3 , $\text{Sb}_2\text{Se}_3/\text{CdS}$, and $\text{Sb}_2\text{Se}_3/\text{CdS}/\text{MoS}_2$ (M-30), are depicted in Fig. 4c, g, and k, and those for M-20 and M-40 are shown in Fig. S10a and b,[†] respectively; these scans show the electronic landscape of the samples. The CPD values for Sb_2Se_3 , $\text{Sb}_2\text{Se}_3/\text{CdS}$, and $\text{Sb}_2\text{Se}_3/\text{CdS}/\text{MoS}_2$ samples lie in the range of -50 to 30 mV, and a similar decrease in CPD from the grain interior (GI) to the grain boundary (GB) can be observed. This indicates that the sample work function at the GB is lower, *i.e.*, the Fermi energy level E_F at the GB is closer to the vacuum level, leading to a downward band bending at the GB. The corresponding schematic diagrams of the energy band structure are presented in Fig. 4d, h and l. Upon further comparison, the average potential difference between the GB and GI for Sb_2Se_3 , $\text{Sb}_2\text{Se}_3/\text{CdS}$, and $\text{Sb}_2\text{Se}_3/\text{CdS}/\text{MoS}_2$ are 23, 35, and 45 mV, respectively. Thus, the increased band bending after the deposition of CdS and MoS_2 would effectively separate electron-hole pairs by attracting electrons (minority carriers) towards the GBs while promoting holes (majority carriers) to flow into GIs. This mechanism is very important for improving electron extraction and minimizing electron-hole recombination, as well as guiding the charge carriers towards the interface to improve photocurrent generation. Thus, it is predicted to contribute to a higher J_{ph} in photocathode, improving the PEC performance.⁴⁴

The photocurrent response and charge transport kinetics of the Sb_2Se_3 -based photocathodes were thoroughly examined. In Fig. 5a, the transient photocurrent decay spectra show that M-20 and M-40 photocathodes exhibited a prominent “spike-like” transient behavior upon light illumination, indicating substantial charge carrier recombination since the temporarily accumulated photoelectrons might easily recombine before reaching a steady state. Conversely, the M-30 photocathode exhibits a very small “spike-like” transient, suggesting reduced charge recombination and improved carrier transport, which is closely related to its optimized surface co-catalyst coverage and photoelectron transport.²⁶ Specifically, the charge transfer efficiency (η_{tran}) is defined as the ratio of the steady-state photocurrent density (J_{ss}) to the instantaneous photocurrent density (J_{inst}). The charge separation efficiency (η_{sep}) can also be obtained using the following equations:^{26,45}

$$J_{\text{tran}} = \frac{J_{\text{ss}}}{J_{\text{inst}}} \quad (3)$$

$$J_{\text{ph}} = J_{\text{abs}} \times \eta_{\text{tran}} \times \eta_{\text{sep}} \quad (4)$$

As a result, the M-30 photocathode achieved the highest η_{tran} of 97.31%, as compared to 81.39% and 93.05% for M-20 and M-40, respectively. In parallel, the η_{sep} for M-30 was also the highest at 82.04%, while M-20 and M-40 exhibited lower values of 51.42% and 69.74%, respectively. The optimized M-30 device simultaneously achieved high charge separation and transport, resulting in improved PEC performance. The theoretical J_{ph} (*i.e.*, J_{abs}) of the Sb_2Se_3 -based photocathodes was also calculated (Fig. 5b, c, S11a, b and Note S1, ESI[†]) by using the standard solar spectrum (AM 1.5G) and wavelength-dependent light harvesting

efficiency (LHE), and assuming 100% conversion of the absorbed photons to current density. Since λ_e is ≈ 1070 nm, the calculations show that the M-30 photocathode achieves a theoretical J_{abs} of 38.23 mA cm^{-2} (Fig. 5c), which is the highest among the three samples (J_{abs} values of 30.04 mA cm^{-2} and 33.82 mA cm^{-2} for M-20 and M-40, respectively). The enhanced J_{abs} for M-30 can be attributed to its ideal MoS_2 thickness and light absorption capacity. Photoelectrochemical impedance spectroscopy (PEIS) investigation of Sb_2Se_3 -based photocathodes was conducted to evaluate the charge transfer resistance and specific charge carrier recombination mechanisms within the system. Fig. 5d represents the Nyquist plots for M-20, M-30, and M-40 photocathodes, displaying two distinct arcs for each sample, consistent with the corresponding Bode plots shown in Fig. 5e. The Bode diagram illustrates two different regions, covering the low and high frequencies in the range of 1 to 100 kHz. The PEIS data were fitted using an equivalent circuit model consisting of a series resistance (R_S) and two pairs of parallel resistor-capacitor ($R-C$) elements, as shown in Fig. 5f. The as-fitted results for M-20, M-30, and M-40 photocathodes are presented in Table S1.[†] In Fig. 5f, R_S represents the series resistance at the Mo/ Sb_2Se_3 back contact interface, and the comparable R_S values ($\approx 5-6$ Ω) across the device indicated a well-established and favorable back interface contact. The high-frequency arc-derived R_{HF} and C_{HF} reflect the charge transfer resistance at the semiconductor heterojunction interface and the associated capacitance within the space charge region. In contrast, R_{LF} and C_{LF} (low frequency arc derivatives) represent the electrochemical charge transfer/reaction resistance within the Helmholtz layer at the electrode-electrolyte interface, along with the corresponding interface/surface-states capacitance.⁴⁶ Notably, the smaller C_{HF} value (5.03×10^{-6} F) for the M-30 photocathode implies a shorter charge accumulation time, while the reduced R_{HF} value suggests less interface defects and more effective charge carrier transport and separation efficiencies at the $\text{Sb}_2\text{Se}_3/\text{CdS}$ heterojunction interface. Furthermore, the minimum R_{LF} value of 4.599 Ω for M-30 as compared to 16.955 Ω for M-20 and 7.929 Ω for M-40 counterparts indicates more efficient HER at the electrode-electrolyte interface under suitable MoS_2 co-catalyst loading.

Bulk and interface charge carrier dynamic characteristics strongly affect the PEC performance of the Sb_2Se_3 -based thin films photocathodes. Therefore, ultraviolet photoelectron spectroscopy (UPS) characterization was performed to examine the energy band alignment of the Sb_2Se_3 absorber, CdS buffer layer (Fig. S11c and d[†]) and MoS_2 (Fig. 5g) thin films to further understand the recombination, transport and separation of charge carriers. According to the secondary electron cut-off (SEC) edge and valence band (V_B) position, the conduction band (E_C) of MoS_2 is -3.94 eV. Compared with the normal hydrogen electrode (NHE), it is -0.50 V_{NHE} , with the conversion implemented by using the following formula:⁴⁷

$$\text{Energy} = -eE_{\text{appl}}(\text{vs. NHE}) - 4.44 \text{ eV} \quad (5)$$

The conduction band minimum (CBM) of the MoS_2 thin film is located above the hydrogen reduction potential, which

Fig. 5 (a) Transient photocurrent response of M-20, M-30, and M-40 photocathodes. (b) Light harvesting efficiency (LHE) of M-20, M-30 and M-40 photocathodes. (g) UPS characterization derived V_B positions and SEC edges of the MoS₂ thin film. (h) M-S plots of the pure MoS₂-30 thin film at a frequency of 1 kHz. (i) Schematic energy band alignment of the Sb₂Se₃/CdS/MoS₂ photocathode. H₂ generation amount as a function of AM 1.5G solar light illumination time over the (j) M-20, (k) M-30, and (l) M-40 photocathodes at 0 V_{RHE} for 2 h in pH 1 buffer solution.

thermodynamically enhances water reduction with hydrogen evolution through solar water splitting, resulting in an enhanced J_{ph} . Mott-Schottky (M-S) measurements were further performed to investigate the capacitance of MoS₂ thin films by examining film capacitance (C) at the semiconductor/electrolyte interface as a function of the applied potential (V). Fig. 5h, S12a and b† demonstrate that $1/C^2$ increases with potential V in the presence of the space charge region (SCR), demonstrating evident n-type characteristics for MoS₂ films.⁴⁸ Furthermore, the

acceptor density (N_A) and flat band potential (E_{fb}) were calculated using the following equation:²

$$\frac{1}{C^2} = -\frac{2}{eA^2\epsilon\epsilon_0 N_A} \left(E_{appl} - E_{fb} - \frac{k_B T}{e} \right) \quad (6)$$

where e is the electron unit, ϵ is the relative dielectric constant, ϵ_0 is the vacuum permittivity, T represents the temperature, k_B represents the Boltzmann constant, A represents the active device area, N_A represents the acceptor density, and C is the SCR

capacitance forms at the semiconductor–electrolyte interface. The analysis shows that the pure MoS₂-30 (30 nm) thin film exhibited the lowest N_A ($3.54 \times 10^{17} \text{ cm}^{-3}$), compared to pure MoS₂-20 (20 nm) ($4.21 \times 10^{18} \text{ cm}^{-3}$) and pure MoS₂-40 (40 nm) ($7.81 \times 10^{17} \text{ cm}^{-3}$) (Fig. S12a and b†). This lower N_A value in pure MoS₂-30 suggests fewer traps for charge carriers, enhanced charge dynamics and a larger space charge region, which together improve charge separation efficiency and reduce recombination losses at the optimal thickness. The valence band (V_B) position of MoS₂ can also be calculated from N_A , E_{fb} , effective mass of hole (m_p^*), and valence band effective density of states function (N_V), by using the following formula:⁴⁹

$$E_V = E_{fb} + kT \ln \left[\frac{N_V}{N_A} \right] \quad (7)$$

$$N_V = 2 \left(\frac{2\pi k T m_p^*}{h^2} \right)^{\frac{3}{2}} \quad (8)$$

The MoS₂ thin film possesses a similar E_V value (-5.74 eV), which matches well with the UPS-derived E_V (-5.74 eV). Finally, band bending and energy band alignment for Sb₂Se₃/CdS/MoS₂ are depicted in Fig. 5i. The CdS and MoS₂ thin films exhibit stronger n-type conductive characteristics, suggesting that MoS₂ would increase the electron carrier density. The valence band offset (VBO) values for n-CdS/p-Sb₂Se₃ and n-CdS/n-MoS₂ are 1.18 eV and 0.57 eV, respectively, which are similar to those reported in previous work ($1.14 \pm 0.10 \text{ eV}$);⁵⁰ these values provide the required energy barrier that efficiently stops photo-generated holes from moving toward the electrode–electrolyte interface for recombination. The conduction band alignment between Sb₂Se₃ and CdS exhibits a “spike-like” band alignment, with a positive conduction band offset (CBO of +0.06 eV), which falls within the optimal range of 0–0.4 eV, suitable for high quality semiconductor heterojunctions. This band alignment decreases energy barriers, enhances charge carrier separation and transport while reducing recombination. After that, the electrons migrate from CdS to the MoS₂ layer, which has a slightly higher conduction band edge, further facilitating electron flow. MoS₂ acts as a co-catalyst and provides active sites for the HER at the photocathode surface. This layered band structure, with suitable band-bending, confirms efficient electron transport from Sb₂Se₃ through CdS to MoS₂, while holes are directed toward the back contact. Thus, the MoS₂ layer improves charge separation and enables effective utilization of photo-generated carriers for hydrogen production, increasing overall PEC efficiency.

Gas chromatography (GC) was used to *in situ* measure the production of H₂ and O₂, and then evaluate the photon utilization capability and faradaic efficiency. As shown in Fig. 5j–l, the champion M-30 photocathode demonstrated continuous H₂ and O₂ evolution at rates of 8.50 and 5.68 $\mu\text{mol min}^{-1}$, respectively, which are higher than those of M-20 (4.97 and 2.79 $\mu\text{mol min}^{-1}$) and M-40 (6.51 and 4.47 $\mu\text{mol min}^{-1}$) photocathodes. Faradaic efficiencies of 91%, 94% and 92% (calculated from the ratio of H₂ to $e^-/2$) were obtained for M-20, M-30, and

M-40 photocathodes, indicating minimal side reactions or competing redox processes on the photoelectrode surface. After 2 h of continuous irradiation, approximately 1020 μmol of H₂ and 682 μmol of O₂ were generated by the champion M-30 photocathode, further confirming the durability and versatility of the champion M-30 device for PEC processed solar water splitting. The recorded video in 0.5 M H₂SO₄ buffer solution under AM 1.5G continuous sunlight irradiation during operation shows continuous hydrogen production (Movie S1, ESI†), confirming the excellent PEC performance of the device.

After the successful demonstration of MoS₂ as an efficient HER co-catalyst, its secondary role as a protective layer was also examined. The current density–time (J – T) curves for those three devices are shown in Fig. 6a, S13a and b,† under AM 1.5G simulated sunlight illumination at 0 V_{RHE} . As illustrated in Fig. 6a, when the light was switched on, the J_{ph} of M-30 quickly increased from 0 mA cm^{-2} to 31.03 mA cm^{-2} , and when the light was turned off, it quickly returned to its initial value. This fast and stable response demonstrates the excellent reversibility and stability of the MoS₂-based Sb₂Se₃ photocathodes. In addition to developing a highly efficient photocathode, assessing its real long-term PEC stability is also crucial for practical applications. Fig. 6b displays the photocurrent stability of the champion device (M-30) over 5 h at 0 V_{RHE} under AM 1.5G continuous light irradiation in an H₂SO₄ buffer solution (pH 1), while Fig. S14a and b† show the stability tests for M-20 and M-40 devices. The thinner MoS₂ layer in M-20 likely provides insufficient surface protection due to limited surface coverage to directly expose part of the underlying Sb₂Se₃/CdS layer to the electrolyte, leading to a higher rate of photo-corrosion and reduced PEC stability. By contrast, the champion M-30 photocathode demonstrated remarkable stability over the 5 h testing period, retaining approximately 90% of its initial J_{ph} under continuous light irradiation. The LSV curves and PEC performance before and after the stability test are shown in Fig. S14c, d and Movie S2.† Its excellent stability is closely related to the MoS₂ layer with appropriate thickness, which effectively protects the Sb₂Se₃/CdS surface, avoiding localized dissolution that could induce thermodynamic photo-corrosion and degradation during prolonged operation. This finding is consistent with other studies in which Sb₂Se₃ photocathodes were protected by additional layers like C₆₀ or TiO₂ to prevent CdS degradation.²⁶ Table S2† presents a comparative analysis of the PEC performance and stability of Sb₂Se₃-based photocathodes using MoS₂ and Pt as co-catalysts. This comparison highlights the effectiveness of MoS₂ as a low-cost alternative to noble metal catalysts while maintaining competitive PEC activity and durability. To further evaluate the intrinsic stability and lifespan of the Sb₂Se₃ absorber (Fig. S13c†), bare MoS₂ film (Fig. S13d†), and M-30 thin-film photocathode (Fig. 6c), a photo-corrosion stress test was conducted using cyclic voltammetry. No significant photo-corrosion currents or redox peaks were observed in any of the samples after 100 cycles, strongly suggesting their exceptional tolerance to photo-corrosion during practical PEC applications. As shown in Fig. 6d–g, the PEC performance and stability of the champion M-30 photocathode also varies significantly across different pH buffer solutions. Specifically, it

Fig. 6 (a) J - T curve of the M-30 photocathode at 0 V_{RHE} under AM 1.5G simulated solar irradiation. (g) Stability of M-30 photocathodes in pH 1, pH 3, and pH 6.5 solution under AM 1.5G simulated light irradiation. (h) Mechanism schematic representation of the PEC performance Mo/Sb₂Se₃/CdS/MoS₂ photocathodes.

exhibited a J_{ph} of 31.01, 19.67, and 9.60 mA cm⁻², and HC-STH efficiencies of 3.06%, 1.67%, and 0.75% in pH 1, pH 3, and pH 6.5 buffer solutions, respectively, confirming the faster and more efficient HER in acidic buffer solution. Moreover, its photocurrent stability (3 h duration) under acidic conditions (pH 1) is superior to that in neutral (pH 6.5) electrolytes. It is similar to some previous reports, *e.g.*, MoS_x co-catalyst modified CZTS and InP photocathodes, both of which exhibit high photocurrent and good stability in acidic conditions as compared to neutral buffer solution.^{29,35} As shown in Fig. 6h, this behavior can be described by the fact that, in acidic environments with a higher concentration of H⁺ ions, photo-excited electrons can more easily and efficiently combine ionically to produce hydrogen gas.⁵¹ The rapid transport of photo-excited electrons in an acidic buffer solution could also mitigate the photo-corrosion of the photoelectrode, and hence increase the

PEC stability of the photocathode.³ These findings are particularly important for optimizing photocathode design for practical solar-driven hydrogen production applications. The enhanced PEC performance under acidic conditions expands the potential applications of these photocathodes to electrocatalysis, sensors, and environmental remediation, where stability under harsh conditions is often a critical requirement.

4. Conclusion

In this work, we successfully demonstrated the enhancement of Sb₂Se₃-based photocathodes for solar hydrogen generation by the introduction of MoS₂ as a cost-effective, noble-metal-free co-catalyst. The optimized Sb₂Se₃/CdS/MoS₂ photocathode achieved a record J_{ph} of 31.03 mA cm⁻² at 0 V_{RHE} and a HC-STH efficiency of 3.08% in a pH 1 buffer solution. The MoS₂ co-

catalyst played an important role in increasing the overall performance by decreasing photo-corrosion, electron-hole recombination, and charge transfer resistance at the semiconductor/electrolyte interface. Our systematic investigation shows that MoS₂ not only facilitated efficient charge carrier transport but also improved light-harvesting efficiency by optimizing the band alignment at the Sb₂Se₃/CdS interface. This dual function of MoS₂, as a co-catalyst and a protective layer, contributed to a stable, high-performance photocathode capable of sustained hydrogen evolution over extended periods under acidic conditions. Additionally, the photocathode exhibited improved stability and performance across a range of pH conditions, making it a promising candidate for practical applications in solar hydrogen production. In short, the combination of Sb₂Se₃ and MoS₂ offers a feasible, eco-friendly alternative to Pt-based devices, advancing the development of efficient and cost-effective photocathodes for hydrogen production.
