## Dielectric films for high performance capacitive energy storage: multiscale engineering

Hao Pan, <sup>a,b</sup> Ahmed Kursumovic, <sup>a</sup> Yuan-Hua Lin, <sup>\*b</sup> Ce-Wen Nan, <sup>b</sup> and Judith L. MacManus-Driscoll<sup>\*a</sup>

Dielectric capacitors are fundamental components in electronic and electrical systems due to their high-rate charging/discharging character and ultrahigh power density. Film dielectrics possess larger breakdown strength and higher energy density than their bulk counterparts, holding great promise for compact and efficient power systems. In this article, we review the very recent advances in dielectric films, in the framework of engineering at multiple scales to improve energy storage performance. Strategies are summarized including atomic-scale defect control, nanoscale domain and grain engineering, as well as mesoscale composite design. Challenges and remaining concerns are also discussed for further performance improvement and practical application of dielectric films.

### 1. Introduction

Both modern electronic technologies and the electrical utility industry have been demanding energy storage strategies for delivering high-power discharge.<sup>1,2</sup> Dielectric capacitors realize energy storage *via* a physical charge-displacement mechanism, functioning with ultrahigh power density (MW kg<sup>-1</sup>) and high voltages that electrochemical energy-storage units (based on long-range charge migration) cannot achieve.<sup>3–5</sup> In power

systems such as clean power generation and electrical vehicles, dielectric capacitors are key components for power modulation, inverting and compensation. In pulsed power technologies, capacitors are the fundamental energy-storage units to realize instant energy release and power amplification.<sup>6</sup> Despite the irreplaceable role of dielectric capacitors, their relatively low energy density (<2 J cm<sup>-2</sup> in commercial polymer or ceramic capacitors) has become the bottleneck for further integration, miniaturization and light-weighting of electronic and electrical systems.<sup>7,8</sup> For instance, the weight and volume percentages of capacitors in power inverters of electrical vehicles are as high as ~23% and ~35%, respectively.<sup>9</sup> The pursuit of new dielectric materials with higher energy storage capability has become an important emerging research topic.

Ahmed Kursumovic is an Advanced Research Fellow in the Materials Science at the University of Cambridge. He has more than 40 years' experience in oxide film growth and device engineering for a range of functional materials.

**Fig. 1** Schematic of dielectric energy storage. The I to II process illustrates the charging (polarization) of a dielectric layer, in which pristine randomly oriented dipoles are aligned and stretched by the electric field; the II to III process represents the discharging process.

As shown in Fig. 1, the governing parameters of the energy density  $U_e$  in dielectrics are: (1) the polarization  $P$  induced by electric field  $E$ , and (2) the breakdown field ( $E_b$ , the highest  $E$  the dielectric can sustain). This is expressed by the equation  $U_e = - \int_{P_m}^{P_r} E_d P \, dP$ , where  $P_m$  and  $P_r$  are the maximum and remnant polarizations, respectively, in the charging–discharging process. The hysteretic response of  $P$  to  $E$  causes partial energy loss  $U_{loss}$ ; the energy storage efficiency  $\eta$  is therefore defined as  $\eta = U_e / (U_e + U_{loss})$ .<sup>10</sup> Ideally, a high  $U_e$  is realized with concurrently high  $P$  (or high dielectric permittivity  $\epsilon_r$ ), low  $U_{loss}$  and large  $E_b$ . However, these parameters are conventionally coupled with each other. Dielectric polarization consists of electronic, ionic, dipole-switching and space charge mechanisms, which contribute in an increasing order to  $P$ , but also cause increasing  $U_{loss}$ .<sup>8</sup> Besides,  $E_b$  usually shows an inverse trend with  $\epsilon_r$ , as dielectrics with higher permittivity intrinsically bear weaker polar bonds and are more susceptible to bond breakage.<sup>11</sup> New materials, strategies and designs are

thus to be explored, in order to mitigate these couplings and to improve the energy storage performance.

The idea of dielectric energy storage originates back to 1960s,<sup>12</sup> when high-polarization ( $\epsilon_r > 1000$ ,  $P > 25 \mu\text{C cm}^{-2}$ ) perovskite ferroelectrics (FEs), *e.g.*  $\text{BaTiO}_3$  (BTO),  $\text{PbTiO}_3$  (PTO) and  $\text{Pb}(\text{Zr},\text{Ti})\text{O}_3$  (PZT), were discovered and studied in detail. It was revealed that BTO ceramics could exhibit  $U_e$  of nearly  $2 \text{ J cm}^{-3}$  at high enough electric fields, showing the huge potential for energy storage.<sup>13</sup> However, ceramics suffer from inevitable structural flaws (pores, microcracks, *etc.*) which limit  $E_b$  to  $0.1 \text{ MV cm}^{-1}$ . Intensive studies have been conducted to reduce flaws in ceramics. The fabrication process is optimized by the addition of sintering aids,<sup>14</sup> hot-press sintering,<sup>15</sup> spark plasma sintering,<sup>16</sup> *etc.* Composition design is also adopted to reduce grain sizes<sup>17,18</sup> and construct core–shell structures.<sup>19</sup> These efforts improve  $E_b$  to near  $0.4 \text{ MV cm}^{-1}$  and  $U_e$  up to  $10 \text{ J cm}^{-3}$  in ceramic dielectrics.<sup>20,21</sup> Multilayer ceramic capacitors (MLCC) were further developed based on tape-casting techniques, in which the layer thickness is reduced to the micrometer scale. Porosity is suppressed, and composition homogeneity is improved, giving rise to  $E_b$  of near  $1 \text{ MV cm}^{-1}$  and the highest  $U_e$  of  $21 \text{ J cm}^{-3}$ .<sup>22–25</sup> On the other hand, polymer dielectrics, *e.g.*, polypropylene and poly(vinylidene fluoride), possess very high  $E_b$  of  $\sim 5 \text{ MV cm}^{-1}$  but weak polarization ( $\epsilon_r < 10$ ,  $P < 10 \mu\text{C cm}^{-2}$ ), leading to unsatisfactory energy performance.<sup>26</sup> By introducing high- $\epsilon_r$  ceramic fillers and modifying the filler composition, morphology and distribution, polymer-based composite dielectrics can realize  $U_e$  of  $10\text{--}30 \text{ J cm}^{-3}$ .<sup>27–30</sup>

Oxide dielectric thin films with thicknesses at the nano or submicron scale have come to the fore in the last decade and they exhibit huge potential for unprecedentedly high-performance in terms of energy storage. Fig. 2 compares the permittivity, breakdown and energy density of representative dielectric films, polymers (and polymer-based composites), MLCC and ceramics. Dielectric films, with great improvement of crystal-

Fig. 2 Comparison of dielectric permittivity, breakdown and energy storage performance between representative dielectric films, polymers (and polymer-based composites), MLCC, and ceramics.<sup>17–25,27–38</sup>

line quality and suppression of flaws, give rise to nearly intrinsic  $E_b$  value of 2–5 MV cm<sup>-1</sup>, which is more than one order of magnitude higher than those of their bulk ceramic counterparts and they rival the values of polymer dielectrics.<sup>31,32</sup> The high  $E_b$ , together with the high permittivity (polarization) maintained in dielectric films, gives rise to ultrahigh  $U_e$  of over 100 J cm<sup>-3</sup>.<sup>33–38</sup> In addition, dielectric films are favourable for their moderate working voltage (dozens to hundreds of volts), matching the commonly used power voltage; they are also more utilizable in embedded integrated circuits with scaled-down geometry.

While there are extensive reviews on energy-storage dielectrics from the point of view of material type (glass, ceramic, polymer, *etc.*),<sup>39</sup> composition (lead-based, lead-free, bismuth-based, *etc.*)<sup>40</sup> and classification of dielectric type (linear, paraelectric, ferroelectric, relaxor, antiferroelectric, *etc.*),<sup>41–43</sup> this field has seen many new remarkable advances, especially in

dielectric films. Here, we present a summary of the very recent progress in dielectric energy-storage films. A new perspective is provided, *i.e.* engineering of dielectric films across different scales (atomic, nano and meso scales) to comprehensively optimize polarization, loss and breakdown properties for further improvement of energy storage performance. Effective and generalizable strategies are highlighted. Remaining concerns for further performance improvement and practical application of dielectric films are also discussed.

## 2. Atomic scale engineering

Crystalline perfection of dielectric films at the atomic scale should be prerequisites for high energy storage performance. Dielectric films can be deposited by both chemical methods such as chemical solution deposition (CSD), spin coating, atomic layer deposition, *etc.*, as well as physical ones, *e.g.*, pulsed laser deposition (PLD) and magnetron sputtering. The deposition process, generally consisting of nucleation and crystal growth, is thermodynamically non-equilibrium. Precursors arriving at substrates have limited time to diffuse, redistribute and reach a stable state, causing compositional fluctuation (especially in complex oxide films) and crystalline defects.<sup>44</sup> Defects usually act as charge carrier traps, which contribute to leakage current at high electric fields, causing large conduction loss and accelerating electric breakdown.<sup>45</sup> A general way is to optimize the deposition factors that affect film growth kinetics, such as precursor concentration and mobility, deposition rate, substrate temperature, *etc.*<sup>46</sup>

It was found that PLD-fabricated BTO films exhibit improved crystalline quality as BiFeO<sub>3</sub> (BFO) is incorporated, owing to a lower-melting-point eutectic forming between Bi<sub>2</sub>O<sub>3</sub> and TiO<sub>2</sub>.<sup>47</sup> This is analogous to liquid sintering in ceramic fabrication, by which mass transfer and crystallization are facilitated. A 25% BFO + 75% BTO film shows the smallest value of full width at half maximum (FWHM) of the reciprocal space map (RSM) peak in X-ray diffraction, meaning the narrowest distribution of lattice parameters and thus the best crystalline uniformity (Fig. 3a). Leakage current density is accordingly suppressed, which is  $1 \times 10^{-4}$  A cm<sup>-2</sup> at 0.5 MV cm<sup>-1</sup> (compared with  $2 \times 10^{-3}$  A cm<sup>-2</sup> in the pure BTO film). An  $E_b$  of 2.2 MV cm<sup>-1</sup> is achieved in the 25% BFO + 75% BTO film, which is 1.5 times larger than that of the BTO film (Fig. 3b). As a result,  $U_e$  is greatly enhanced from 5.6 J cm<sup>-3</sup> to 52 J cm<sup>-3</sup>. Similar research was also reported in CSD-fabricated PTO-based films; by incorporating excess PbO<sup>48</sup> or a PbO seeding layer,<sup>49</sup> grain nucleation and film crystallinity are promoted, leading to a lower leakage current and higher energy density.

The nature of deposition is another factor affecting the film growth kinetics. For instance, reducing the pulse frequency in PLD allows longer diffusion time for adatoms, realizing dense, layer-like growth, instead of a porous, columnar structure.<sup>50</sup> However, this is at the sacrifice of fabrication efficiency. A “layer-by-layer” deposition (LLD) strategy was proposed recently, which combines (1) deposition pulses at high fre-

standing of basic functionalities and in engineering new interfacial-driven properties. For this purpose, she designs, fabricates and analyses novel nanostructured films (superlattice approaches and self-assembled ordered nanocomposites).

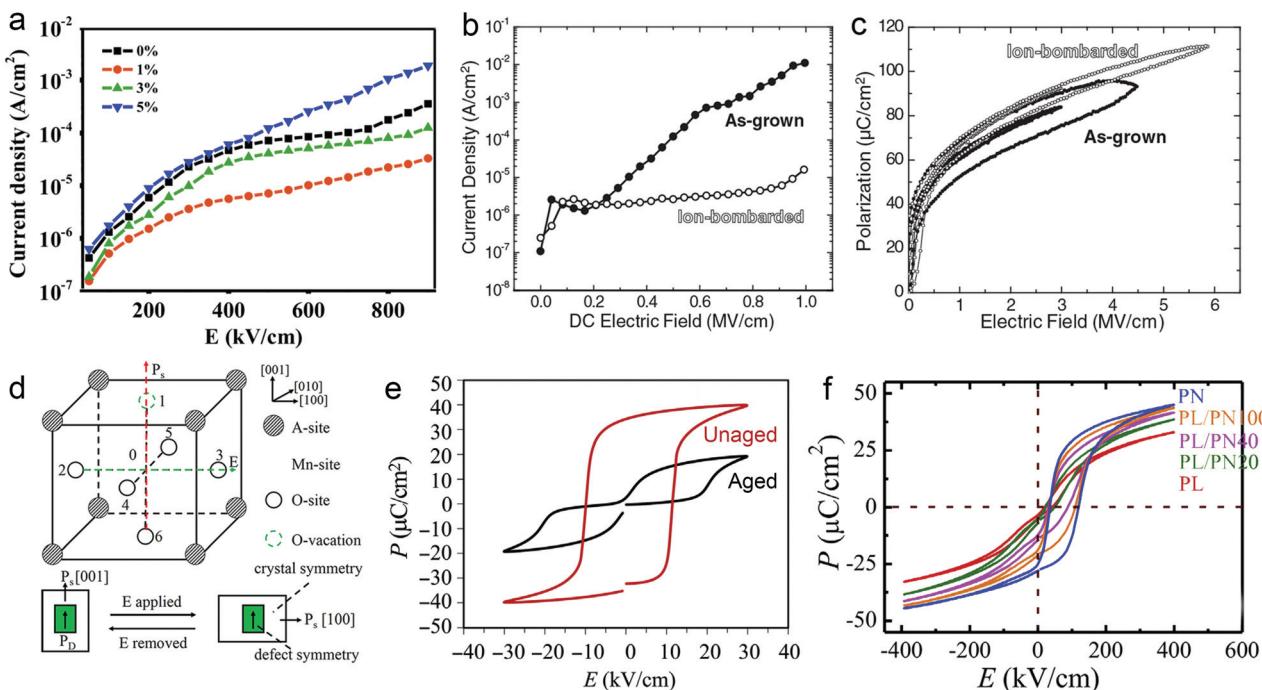

Fig. 3 (a) RSM of BFO–BTO dielectric films around the (103) peaks.<sup>47</sup> (b) Breakdown field of the BFO–BTO films as a function of the FWHM of  $q_x$  of the RSM in (a).<sup>47</sup> Copyright © 2018, Elsevier. (c) Schematic comparison of the LLD and SD strategies for pulsed laser film deposition.<sup>51</sup> (d) Rocking-curve ( $\omega$  scan) and (e) leakage current of the 25% BFO + 75% BTO films fabricated by SD and LLD strategies, respectively.<sup>51</sup> Copyright © 2020, Elsevier.

quencies (e.g. ~50 Hz) to form a monolayer (unit-cell thick) in 10–20 ms, and (2) a long interval (>1 s) for full relaxation and reconstruction of the monolayer towards stable structure (Fig. 3c).<sup>51</sup> This LLD strategy enables high film perfection at high fabrication rate; while in standard PLD deposition (SD) with similar overall rate, island growth with inferior quality occurs. LLD-fabricated 25% BFO + 75% BTO films show narrower rocking curves than the films made by SD, with the FWHM reduced by 60% (Fig. 3d). The improvement of crystalline quality suppresses the leakage current by 2 orders of magnitude (Fig. 3e) and enhances the  $E_b$  to 3.1 MV cm<sup>-1</sup>, giving rise to an even higher  $U_e$  of ~80 J cm<sup>-3</sup>.

However perfect the crystallization is, point defects inevitably remain in dielectric films. Oxygen vacancies are common defects in oxide dielectrics, from which trapped electrons can be activated into the conduction band, leading to leakage conduction. Post-deposition annealing in an oxygen-rich atmosphere is widely used to reduce the oxygen vacancy concentration.<sup>52</sup> Appropriate element doping is another acknowledged strategy to eliminate or compensate oxygen vacancies.<sup>51,53–55</sup> In  $(\text{Bi}_{1/2}\text{Na}_{1/2})\text{TiO}_3$  (BNT) films, Mn doping at the Ti site causes  $\text{Mn}''\text{Ti}$  defects, which interact with oxygen vacancies and form  $\text{Mn}''\text{Ti} - \text{V}_\text{O}''$  defect complexes.<sup>55</sup> Defect complexes, with strong internal electrostatic force, are effective traps of charge carriers, which form deeper defect energy levels and thus increase the resistivity.<sup>56,57</sup> The leakage current of BNT films with 1% Mn doping is decreased by 2 orders of

magnitude (Fig. 4a), leading to an improvement of  $E_b$  by 67% (from 1.4 to 2.3 MV cm<sup>-1</sup>) and  $U_e$  by 100% (from 15 to 30 J cm<sup>-3</sup>).<sup>55</sup> Note that the doping strategy is very delicate; excess ion doping (e.g. >1% Mn in the BNT film) could introduce superfluous defects, thus deteriorating the resistivity and energy performance (Fig. 4a). Besides element doping, extrinsic strategies such as tuning deposition parameters<sup>58</sup> and ion irradiation<sup>59</sup> can also introduce defect complexes. A high-energy helium ion bombardment strategy was reported recently,<sup>37</sup> which knocks ions from their lattice sites in  $0.68\text{Pb}(\text{Mg}_{1/3}\text{Nb}_{2/3})\text{O}_3\text{-}0.32\text{PbTiO}_3$  (PMN-PT) films, causing deep-energy-level defect complexes, e.g.,  $\text{V}''\text{Pb} - \text{V}_\text{O}''$ ,  $\text{V}''\text{Mg} - \text{V}_\text{O}''$ , and possible  $\text{V}_\text{O}'' - \text{V}''\text{Ti} - \text{V}_\text{O}''$ . The leakage of the PMN-PT films is thus suppressed by 3 orders of magnitude after ion bombardment (Fig. 4b) and  $E_b$  is improved from 3.8 to 5.9 MV cm<sup>-1</sup>, contributing to an ultrahigh  $U_e$  of 133 J cm<sup>-3</sup> (Fig. 4c).

In addition to resistivity and breakdown behaviors, defects can also play a role in altering polarization properties. Chemical pressure is introduced by doping ions of different radius, which alters the Landau energy profiles. It was indicated that a tensile chemical stress is created by the substitution of larger  $\text{Fe}^{2+}$  and  $\text{Fe}^{3+}$  ions for smaller  $\text{Ti}^{4+}$  in  $\text{Bi}_{3.25}\text{La}_{0.75}\text{Ti}_3\text{O}_{12}\text{-BiFeO}_3$  films, which decreases the free energy of the potential well at biased fields, increases the polarization and enhances  $U_e$ .<sup>60</sup> On the other hand, a compressive chemical pressure induced by  $\text{Li}^+/\text{La}^{3+}$  ion doping in antiferroelectric (AFE)  $\text{PbZrO}_3$  films could stabilize the AFE phase

and delay the field-induced phase transition, also enhancing the energy performance.<sup>61</sup> As for defect complexes, they are equivalent to dipoles ( $P_D$ ) consisting of inversely charged point defects, which is conventionally oriented along the local spontaneous polarization ( $P_s$ ) and crystal symmetry (Fig. 4d).<sup>62</sup> Since  $P_D$  reacts relatively more slowly to electric field, it offers a restoring force for  $P_s$  to switch back to its original orientation, causing an ageing feature that is characteristic with a pinched  $P$ - $E$  loop and a much suppressed  $P_r$  (Fig. 4e).<sup>63</sup> This provides an opportunity to reduce  $U_{\text{loss}}$  and enhance  $U_e$ .<sup>62</sup> On the other hand, when the defect complex dipoles are aligned in the same direction due to substrate stress, crystal symmetry or poling, internal bias fields and imprint features are built in the films.<sup>64</sup> As shown in Fig. 4f, imprint in FE films increases the  $P_m - P_r$  value, which also improves  $U_e$ .<sup>37,65</sup>

### 3. Nanoscale engineering

At the nanoscale, the research focus is on ferroelectric domains, as schematically illustrated in Fig. 5a. Typical FEs such as PTO, BTO and BFO possess micrometer-size domains that are strongly electrostatically coupled with each other. FEs exhibit deep Landau energy wells, high polarization switching barriers, large  $P$ - $E$  hysteresis, as well as inferior  $U_e$  and  $\eta$ . A general developing trend is relaxor ferroelectrics (RFEs). RFEs are a subclass of FEs with complex compositions, such as

PMN-PT and BNT, as mentioned above, and also  $(\text{Pb},\text{La})(\text{Zr},\text{Ti})\text{O}_3$  (PLZT) and  $(\text{Ba},\text{Sr})\text{TiO}_3$ . The most typical microscopic feature of RFEs is the breaking of long-range polarization order and the emergence of short-range-ordered FE nanodomains.<sup>66</sup> Nanodomains are weakly inter-coupled and are more easily switched by external fields, with a reduction of energy barrier. RFEs therefore exhibits lower loss (hysteresis), slimmer  $P$ - $E$  loops, as well as relatively higher dielectric permittivity (polarization), which is optimal for capacitive energy storage (Fig. 5a).

An effective strategy to obtain RFEs is the formation of solid solutions. For example, the PLZT solid solution, with 10–20% Pb substituted by La, is driven from FE to RFE phase,<sup>67</sup> which realizes a high  $U_e$  of  $85 \text{ J cm}^{-3}$  at the  $E$  of  $4.5 \text{ MV cm}^{-1}$ .<sup>33</sup> It has been reported that solid solution films combining the FE BFO with paraelectric  $\text{SrTiO}_3$  (STO) also realizes RFE.<sup>68</sup> Clear nanodomain evolution is observed with the composition change. 0.70BFO–0.30STO films contain rhombohedral FE domains that are  $>20 \text{ nm}$  in diameter, as characterized by scanning transmission electron microscopy (Fig. 5b). 0.40BFO–0.60STO films, on the other hand, exhibit nanodomains with diameters of  $<10 \text{ nm}$ , which are embedded in a nonpolar matrix (Fig. 5c). This is because that the incorporation of Sr onto the Bi site and Ti onto the Fe site breaks the long-range compositional, chemical, and ferroelectric order of BFO. Relaxor 0.40BFO–0.60STO films therefore exhibit substantial reductions of  $P_r$  and  $U_{\text{loss}}$ , leading to concurrent improvements of  $U_e$  and  $\eta$ ,

**Fig. 5** (a) Schematic illustration of the design of RFEs with nanodomain and polymorphic nanodomain structures to lower the polarization switching barrier, reduce the hysteresis and improve the energy storage performance.<sup>34</sup> (b and c) STEM images of the nanodomain structures of the  $(1-x)$  BFO- $x$ STO relaxor films with  $x = 0.30$  and  $0.60$ , respectively (scale bars:  $10$  nm). Copyright © 2019, American Association for the Advancement of Science.

with high values of  $70.3 \text{ J cm}^{-3}$  and 70%, respectively. A wide range of new RFE films including BTO-based,<sup>69,70</sup> BNT-based,<sup>71,72</sup> and  $(\text{K}_{1/2}\text{Na}_{1/2})\text{NbO}_3$ -based<sup>73</sup> films have been similarly developed, in which energy storage performances are all enhanced with nanodomain engineering.

Here it is worth pointing out that the nanodomain strategy usually reduces the polar domain entities, and thus sacrifices polarization. The coupling between polarization and loss becomes the main challenge in RFEs for further improvement of energy performance. To mitigate the coupling, a polymorphic nanodomain strategy was recently proposed.<sup>34</sup> By judiciously constructing coexisting nanodomains with competitive free energies but different polarization orientations, *e.g.*, rhombohedral (R) and tetragonal (T), the polarization anisotropy between the  $\langle 111 \rangle_R$  and  $\langle 001 \rangle_T$  orientations were greatly weakened (Fig. 5a). This led to further flattening of polarization switching energy barriers and lower  $U_{\text{loss}}$ , while maintaining relatively high polarization. In the accordingly designed BFO-BTO-STO ternary solid-solution films, a polymorphic nanodomain structure was realized. Coexisting R and T nanodomains were observed with very small sizes of 2–5 nm and strong local polarization disorder (Fig. 5d–g). The optimized composition  $0.25\text{BFO}-0.30\text{BTO}-0.45\text{STO}$  showed a com-

bination of high polarization and low loss, with a  $P_m$  to  $P_r$  ratio of 7.9, much larger than those of binary films (*e.g.*, 3.5 for  $0.55\text{BFO}-0.45\text{STO}$  and 6.8 for  $0.25\text{BFO}-0.75\text{STO}$ ), giving rise to an ultrahigh  $U_e$  of  $112 \text{ J cm}^{-3}$  and high  $\eta$  of  $\sim 80\%$ .

Besides nanodomains, nanograin design to improve energy storage performance has also been investigated. In ceramic dielectrics,  $E_b$  usually follows the rule  $E_b \propto 1/\sqrt{G}$ , where  $G$  is the grain size.<sup>74</sup> This indicates that smaller grains tend to enhance  $E_b$ , partially because grain boundaries in dielectrics are more resistive than grains.<sup>75</sup> Amorphous dielectrics, in which there are no crystalline grains, usually exhibit very large  $E_b$  values.<sup>76</sup> However, their inferior permittivity imposes serious limitation on the achievable  $U_e$ . Nano-crystalline dielectrics are thus designed to reach an optimal compromise between  $E_b$  and  $P$ . Delicate thermal treatment is usually adopted to realize nanograins. In  $\text{Pb}_{0.88}\text{Ca}_{0.12}\text{ZrO}_3$  films,<sup>77</sup> annealing at  $550^\circ\text{C}$  realizes nanometer-size pyrochlore grains that randomly distribute in the amorphous matrix, resulting in a  $P_m$  of  $37 \mu\text{C cm}^{-2}$  and an  $E_b$  of  $5.0 \text{ MV cm}^{-1}$ . Lower annealing temperatures (*e.g.*,  $525^\circ\text{C}$ ) leads to pure amorphous films with slightly higher  $E_b$  of  $5.2 \text{ MV cm}^{-1}$  but a much smaller  $P_m$  of  $\sim 20 \mu\text{C cm}^{-2}$ ; while a higher annealing temperature (*e.g.*,  $650^\circ\text{C}$ ) results in fully crystallized films with a higher  $P_m$  of

~68  $\mu\text{C cm}^{-2}$  but a much smaller  $E_b$  of 2.1  $\text{MV cm}^{-1}$ . The nanograin film annealed at 550  $^{\circ}\text{C}$  gives the highest  $U_e$  of 91  $\text{J cm}^{-3}$ .<sup>77</sup> Similar results have also been seen in  $\text{Sr}_{0.925}\text{Bi}_{0.05}\text{TiO}_3$ ,  $\text{BiMg}_{0.5}\text{Ti}_{0.75}\text{O}_3$  and  $\text{Pb}_{2.1}\text{TiO}_{3.1}$  films,<sup>35,76,78</sup> confirming the effectiveness of the nanograin strategy. Also, chemical composition design can reduce the grain size and improve  $E_b$ , as demonstrated in dielectric ceramics.<sup>17,18</sup> To the best of our knowledge, this has not yet been reported in dielectric films but it is expected to be a feasible strategy in future.

## 4. Mesoscale engineering

Research at the mesoscale has focused on composite systems. Using the layer-by-layer deposition process, dielectric films can be made with the distinct advantage of easy fabrication of 2-2 composites, including heterostructures (bilayers and multilayers) and superlattices.<sup>79,80</sup>

In heterostructures, dielectric layers are connected in series. To ensure a continuous  $P$ , a layer with lower permittivity is subject to a higher effective electric field, and *vice versa*. The distribution of electric fields can be modulated by altering the thickness and dielectric parameters of each layer, providing a

chance to improve the energy performance. For example, by adding a 6 nm low-permittivity  $\text{Al}_2\text{O}_3$  layer in series with a 400 nm high-permittivity BFO-STO layer, the voltage in the BFO-STO layer is decreased, which leads to a delayed polarization saturation and a ~30% increase of  $U_e$  (Fig. 6a and b).<sup>81</sup> It is also revealed that a PZT/ $\text{Al}_2\text{O}_3$ /PZT double heterojunction greatly improves  $E_b$  from 2.4 to 5.7  $\text{MV cm}^{-1}$ , because of the reduced effective  $E$  in the PZT layers, the high resistivity of  $\text{Al}_2\text{O}_3$ , and the built-in fields at the heterointerfaces. This leads to a much enhanced  $U_e$  from 10 to 64  $\text{J cm}^{-3}$ .<sup>32</sup> Recently, it was suggested to take advantage of the negative capacitance (NC) feature of FEs to enhance the energy storage capability.<sup>82</sup> The NC state, which is unstable in a single FE layer, can be stabilized in a FE/paraelectric or a FE/linear-dielectric heterostructure film (*e.g.*,  $\text{Hf}_{0.5}\text{Zr}_{0.5}\text{O}_2/\text{Ta}_2\text{O}_5$ , Fig. 6c). With an optimized match of the capacitances of the FE and linear-dielectric layers, the field in the linear-dielectric layer is amplified due to the decreasing field in the NC-state FE layer, leading to an ultrahigh differential capacitance (Fig. 6d). A  $U_e$  of  $>100 \text{ J cm}^{-3}$  with  $\eta$  of ~95% can be experimentally observed in this heterostructure film.

In superlattices, the existence of high-density interfaces and the electrostatic coupling between layers provide more

(c) Structure schematic and (d) schematic of enhancement of energy density by negative capacitance effect in the  $\text{Hf}_{0.5}\text{Zr}_{0.5}\text{O}_2/\text{Ta}_2\text{O}_5$  heterostructure.<sup>82</sup> (e) Structure schematic and STEM images of  $(\text{BZT}/\text{BCT})_N$  superlattice film.<sup>31</sup> (f and g)  $P$ - $E$  loops of  $N = 8$  and  $N = 2$  films, respectively.<sup>31</sup> (h) Energy density and efficiency of the  $(\text{BZT}/\text{BCT})_N$  superlattice.<sup>31</sup> Copyright © 2016 WILEY-VCH.

freedom for subtle control of dielectric properties. BTO/(Ba<sub>0.3</sub>Sr<sub>0.7</sub>)TiO<sub>3</sub> superlattice films were fabricated with a periodicity of ~8 nm and a total thickness of 600 nm.<sup>83</sup> The films exhibited typical RFE features with dispersed phase transition and frequency dispersion. A high breakdown field of >5 MV cm<sup>-1</sup> and an estimated  $U_e$  of ~46 J cm<sup>-3</sup> were obtained. (Ba<sub>0.7</sub>Ca<sub>0.3</sub>)TiO<sub>3</sub>/Ba(Zr<sub>0.2</sub>Ti<sub>0.8</sub>)O<sub>3</sub> (BZT/BCT) superlattice films were also studied recently with respect to the periodicity. With a fixed total thickness of ~100 nm, (BZT/BCT)<sub>N</sub> films with  $N = 2, 4$  and  $8$  were designed (Fig. 6e). Along with the decrease of periodic length, the long-range FE coupling interaction becomes more dominant, which results in much slimmer  $P$ - $E$  loops in the  $N = 8$  film than those for  $N = 2$  (Fig. 6f and g). Moreover, it was demonstrated that the interfaces impede the growth of electric breakdown trees; therefore,  $E_b$  increases with  $N$  and reaches 4.7 MV cm<sup>-1</sup> for  $N = 8$ . With these synergistic benefits, the  $N = 8$  film exhibits the highest  $U_e$  of 52 J cm<sup>-3</sup> and high  $\eta$  of 72%, which are 98% and 21% higher than those for  $N = 2$ , respectively (Fig. 6h).<sup>31</sup> However, a further increase of  $N$  (or decrease of periodicity) may be disadvantageous as the interface diffusion becomes more prominent, thus weakening the blockage of electric breakdown tree. This was revealed in Ba(Zr<sub>0.15</sub>Ti<sub>0.85</sub>)O<sub>3</sub>/Ba(Zr<sub>0.35</sub>Ti<sub>0.65</sub>)O<sub>3</sub> superlattice films, in which  $N = 6$  leads to the largest  $E_b$  (8.3 MV cm<sup>-1</sup>) and the highest  $U_e$  of 84 J cm<sup>-3</sup>.<sup>36</sup>

## 5. Conclusions and perspectives

The demand for high-power applications in electronic and electrical systems has stimulated intense study and fast development of dielectric energy storage materials. This review summarizes multifaceted strategies at the atomic, nano and meso scales to improve the energy storage performance of dielectric films. High energy storage densities of ~10<sup>2</sup> J cm<sup>-3</sup> have been achieved in a series of film materials. For further performance enhancement, a key challenge is how to mitigate and break the coupling between polarization, loss and breakdown properties. Future progress is anticipated with designs that rationally and hierarchically incorporate multiscale strategies, including but not limited to those discussed in this article. It is also worth mentioning that these strategies are well applicable to improve the performance of bulk ceramics, thick films and even polymer-based dielectrics.

When it comes to practical utilization of dielectric films, other factors also need to be considered. For high-frequency alternating current or impulse applications, power density is an equally important parameter. A quantitative expression of the power density  $P_w$  is  $P_w = \pi f \epsilon_0 \epsilon_r E^2 / (2 \tan \delta)$ , where  $f$  and  $\tan \delta$  are the operating frequency and loss tangent (assuming  $\tan \delta$  is frequency and field independent).<sup>84</sup> The importance of a low  $\tan \delta$  (*i.e.*, a low equivalent series resistance) for dielectric film capacitor is emphasized. What is more, capacitors work in various and often harsh conditions, such as high  $E$  and high temperatures, where performance reliability and stability are among the most fundamental qualifications. Dielectrics in

practical use are limited to  $E$  that is only 1/3–1/2 of the statistical  $E_b$  to prevent unwanted device failure. A large  $E_b$  of dielectric film is therefore critical for realizing a large enough practical energy storage capability while ensuring long-term performance reliability. Further work on revealing the breakdown mechanisms and improving  $E_b$  of dielectric films is thus required.

Thermal stability is another concern for dielectric films considering high-temperature applications. Thermally-stable permittivity and polarization have been realized in RFE films that undergo diffused phase transitions. However, thermal-stimulated leakage current generally increases exponentially with temperature. As a result, conduction loss becomes dominant, causing potential electrical-thermal breakdown and deteriorating energy performance. Further studies such as large-bandgap dielectric screening, defect engineering and nano-composite film design are expected to address this problem.

Last but not the least, it is important to modify the deposition techniques of dielectric films for the compatibility with integrated circuit and device fabrication. Flexible electronics is an emerging and important field, for which flexible energy-storage dielectric films are required. Success for flexible energy-storage films has been proven using modified deposition on flexible substrates,<sup>85,86</sup> which might also be possible using lift-off techniques.<sup>87,88</sup>
