"FeV-cofactor"-inspired bionic Fe-doped  $\text{BiVO}_4$  photocatalyst decorated with few-layer 2D black phosphorus for efficient nitrogen reduction

In-built bionic FeV cofactor in Fe- $\text{BiVO}_4$  catalyst decorated with 2D black phosphorus can not only adsorb and activate  $\text{N}_2$  molecules, but also promote carrier separation and transfer, thus improving photocatalytic nitrogen reduction performance.

## "FeV-cofactor"-inspired bionic Fe-doped BiVO<sub>4</sub> photocatalyst decorated with few-layer 2D black phosphorus for efficient nitrogen reduction†

Hongda Li, <sup>a,c</sup> Shuai Jian, <sup>a</sup> Boran Tao, <sup>a,c</sup> Guoxiao Xu, <sup>a</sup> Baosheng Liu, <sup>a</sup> Shaonan Gu, <sup>\*b</sup> Guofu Wang<sup>\*a</sup> and Haixin Chang <sup>\*c</sup>

Drawing inspiration from the biological nitrogenase mechanism, bionic photocatalytic nitrogen fixation technology plays a significant role in activating nitrogen molecules and promoting the nitrogen reduction reaction. However, developing effective semiconductor photocatalysts remains a considerable challenge in the field of bionic nitrogen fixation. Herein, a novel bionic "FeV-cofactor" system for performing photocatalytic nitrogen reduction was proposed for the first time based on an Fe-doped BiVO<sub>4</sub> photocatalyst decorated with few-layer 2D black phosphorus (BP). As expected, Fe doping and BP decoration significantly improved the NH<sub>3</sub> yield of BiVO<sub>4</sub>. With an NH<sub>3</sub> yield of 337.9 μmol g<sup>-1</sup> h<sup>-1</sup> (6.83 times that of BiVO<sub>4</sub>), FeBiVO<sub>4</sub>-0.05BP ranks among the top-performing nitrogen-fixing materials in oxide-based photocatalysts. DFT calculations show that N<sub>2</sub> molecules can be adsorbed and activated by Fe doping, thus forming the in-built bionic "FeV-cofactor". The experimental results further confirm that introducing a bionic "FeV-cofactor" system enhances the electron transfer between redox couples (V<sup>5+</sup>/V<sup>4+</sup> & Fe<sup>3+</sup>/Fe<sup>2+</sup>) and N<sub>2</sub>, thus improving the carrier separation efficiency. Oxygen vacancies coupled with V<sup>4+</sup> ions also contribute to increasing light absorption. The 2D BP decoration plays a crucial role in the whole process of nitrogen reduction due to its exceptional electron transfer ability while increasing the active sites of the reaction.

## Introduction

Ammonia (NH<sub>3</sub>) is a potential hydrogen energy carrier and an important feedstock in producing plastics, fertilizers, and other chemicals whose effects permeate all human lives.<sup>1,2</sup> The Haber–Bosch process, currently used for the industrial production of NH<sub>3</sub>, involves high-purity N<sub>2</sub> and H<sub>2</sub> reacting under extreme conditions (20–40 MPa, 400–600 °C), resulting in high energy consumption and CO<sub>2</sub> emissions.<sup>3</sup> Exploring an environmentally friendly NH<sub>3</sub> production route is necessary to replace the traditional process.

In nature, diazotrophic bacteria and archaea reduce N<sub>2</sub> to NH<sub>3</sub> through nitrogenase-catalyzed reactions.<sup>4</sup> Bionic nitrogen fixation has attracted significant attention due to its similarity to natural processes. Using abundant solar energy, bionic photocatalytic nitrogen fixation can achieve sustainable NH<sub>3</sub> synthesis under ambient conditions, which is both energy sustainable and environmentally friendly.<sup>5–7</sup> Despite its potential, photocatalytic nitrogen fixation suffers from low conversion efficiency, mainly because the stable triple bond N≡N (941 kJ mol<sup>-1</sup>) is difficult to be activated or cleaved under ambient conditions.<sup>8</sup> Furthermore, semiconductor photocatalysts typically exhibit poor interfacial charge transfer and/or light absorption, limiting their applicability in charge- and energy-intensive nitrogen reduction reactions.<sup>9</sup>

Three different nitrogenases have similar characteristics and can be classified as the FeMo-cofactor, FeFe-cofactor, and FeV-cofactor based on the metallic composition of catalytic cofactors; the FeMo-cofactor is the most extensively studied.<sup>10</sup> Consequently, FeMo-based bionic semiconductor photocatalysts for nitrogen reduction have attracted significant attention. Studies on FeMo-based bionic nitrogen-fixing photocatalysts such as MIL-88A (Fe/Mo)<sup>11</sup> and Fe-doped Bi<sub>2</sub>MoO<sub>6</sub><sup>12</sup> have been conducted. Our previous research also suggested that

constructing a bionic FeMo-cofactor effectively enhances the nitrogen reduction activity. The formation of a bionic “FeMo-cofactor” in Fe-doped  $\text{MoTe}_2$ <sup>13</sup> and Fe/Mo bimallene-coated  $\text{Bi}_2\text{Mo}_{0.3}\text{W}_{0.7}\text{O}_6$  nanocrystals<sup>14</sup> can effectively promote the separation and transfer of photoinduced carriers. However, despite structural similarities between the FeV-cofactor and FeMo-cofactor in nitrogenase, these variants exhibit different nitrogen reduction mechanisms,<sup>15</sup> and it is unclear how different metal compositions affect catalytic performance and the possible mechanisms. Bionic catalytic cofactors in various forms also exhibit diverse reaction mechanisms. More importantly, the formation of bionic FeV-cofactor has not been reported in the field of semiconductor photocatalytic nitrogen reduction, leaving its relevant mechanisms unknown. Similarly, questions persist about which metal in the bionic FeV-cofactor sites are active for nitrogen reduction and whether bimetallic synergies between V and Fe sites may play a role.

$\text{BiVO}_4$  is a well-known semiconductor photocatalyst. The monoclinic form of  $\text{BiVO}_4$  possesses a suitable band gap (2.3–2.4 eV) and an ideal electronic structure.<sup>16,17</sup> It has been reported that  $\text{BiVO}_4$  exhibits notable photocatalytic nitrogen fixation performance,<sup>18,19</sup> and it is one of the ideal candidates for FeV-based bionic nitrogen-fixing photocatalysts. Furthermore, black phosphorus (BP), an emerging low-cost and highly efficient metal-free co-catalyst, has shown excellent assistant effects in photocatalytic nitrogen reduction,<sup>20–22</sup> due to its excellent optical/electronic properties such as broad-spectrum light capture capability, high carrier mobility ( $\sim 1000 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ ) and tunable band gap (0.3–2.0 eV).<sup>23–25</sup> Herein, we present a novel bionic Fe-doped  $\text{BiVO}_4$  photocatalyst decorated with BP for nitrogen reduction. By integrating DFT calculations and experimental results, we demonstrated that the inbuilt bionic “FeV-cofactor” not only adsorbed and activated  $\text{N}_2$  molecules but also promoted electron transfer between redox couples ( $\text{V}^{5+}/\text{V}^{4+}$  &  $\text{Fe}^{3+}/\text{Fe}^{2+}$ ) and  $\text{N}_2$ , thus improving the carrier separation efficiency. Oxygen vacancies coupled with  $\text{V}^{4+}$  ions also contribute to increasing light absorption. Simultaneously, 2D BP decoration plays a key role in the whole nitrogen reduction of bionic FeV cofactor photocatalysts due to its superior electron transfer ability while increasing the active sites of the reaction. This work provides an effective approach to designing bionic FeV-based inorganic semiconductor photocatalysts for nitrogen reduction.

## Experimental section

### Preparation of $\text{BiVO}_4$ and Fe-doped $\text{BiVO}_4$ ( $\text{FeBiVO}_4$ ) samples

$\text{BiVO}_4$  and  $\text{FeBiVO}_4$  samples were synthesized using a hydrothermal method. In the standard procedure, 0.970 g (2 mmol) of  $\text{Bi}(\text{NO}_3)_3 \cdot 5\text{H}_2\text{O}$  and 0.234 g (2 mmol) of  $\text{NH}_4\text{VO}_3$  were dissolved in 30 mL of  $\text{HNO}_3$  solution (2 mol  $\text{L}^{-1}$ ) and 30 mL of deionized water, respectively. The  $\text{NH}_4\text{VO}_3$  solution was added dropwise to  $\text{Bi}(\text{NO}_3)_3$  solution and stirred for 60 min. To synthesize 2 mol% Fe-doped  $\text{BiVO}_4$  ( $\text{FeBiVO}_4$ ) samples, 0.04 mmol

$\text{Fe}(\text{NO}_3)_3 \cdot 9\text{H}_2\text{O}$  was added into the above solution mixture. The pH value of the resulting solution was adjusted to 7 with  $\text{NaOH}$  (4 mol  $\text{L}^{-1}$ ) and stirred for 60 min. Then, the final mixture was transferred into a 100 mL Teflon-lined stainless-steel autoclave and maintained at 200 °C for 18 h. After the reaction, the product was collected by filtration, washed three times with deionized water, and dried at 80 °C for 12 h.

### Preparation of 2D black phosphorus (BP) nanosheets

Bulk BP was synthesized using a simple low-pressure transport route. 0.5 g of red phosphorus, 0.02 g of Sn, and 0.01 g of  $\text{SnI}_4$  were sealed in a vacuum quartz tube. The quartz tube was heated to 650 °C at a rate of 2 °C  $\text{min}^{-1}$  and maintained at 650 °C for 5 h, then cooled to 500 °C at a cooling rate of 0.5 °C  $\text{min}^{-1}$ , and then cooled naturally to room temperature. BP single crystals were collected and stored in a glove box for subsequent use. 2D BP nanosheets were produced by liquid exfoliation of bulk BP.<sup>26</sup> Specifically, 30 mg of BP was dispersed in 100 mL of ethanol under Ar, and the suspension was ultrasonicated for 10 h. Finally, the stable suspension was centrifuged at 5000 rpm for 10 min to obtain nanosheets.

### Preparation of $\text{BiVO}_4/\text{BP}$ and $\text{FeBiVO}_4/\text{BP}$ heterojunctions

$\text{BiVO}_4/\text{BP}$  and  $\text{FeBiVO}_4/\text{BP}$  heterojunctions were synthesized using the electrostatic self-assembly method.<sup>27</sup> A specified amount of BP nanosheets and 100 mg of  $\text{BiVO}_4$  or  $\text{FeBiVO}_4$  were added into 100 mL of ethanol and sonicated for 120 min under Ar to obtain a stable homogeneous dispersion. The resulting products ( $\text{BiVO}_4/\text{BP}$  or  $\text{FeBiVO}_4/\text{BP}$ ) were collected by centrifugation and vacuum-dried at 80 °C for 6 h. The composite heterojunction catalysts were obtained as follows:  $\text{BiVO}_4/5 \text{ wt\%BP}$  ( $\text{BiVO}_4\text{-}0.05\text{BP}$ ),  $\text{FeBiVO}_4/2 \text{ wt\%BP}$  ( $\text{FeBiVO}_4\text{-}0.02\text{BP}$ ),  $\text{FeBiVO}_4/5 \text{ wt\%BP}$  ( $\text{FeBiVO}_4\text{-}0.05\text{BP}$ ), and  $\text{FeBiVO}_4/10 \text{ wt\%BP}$  ( $\text{FeBiVO}_4\text{-}0.10\text{BP}$ ).

### Characterization

Powder X-ray diffraction (XRD) patterns were detected using an XRD instrument (SmartLab SE, Rigaku, Japan) equipped with  $\text{Cu K}\alpha$  radiation ( $\lambda = 1.5418 \text{ \AA}$ ). The microstructure and morphology were characterized by field-emission scanning electron microscopy (FESEM; MIRA LMS, TESCAN, Czech Republic), transmission electron microscopy (TEM; JEM 2100F, JEOL, Japan), and atomic force microscopy (AFM; Dimension Icon, Bruker, Germany). The specific surface areas were measured using the Brunauer–Emmett–Teller (BET) method (ASAP2460, Micromeritics, USA). The actual contents of Bi, Fe, P, and V elements were collected using an inductively coupled plasma optical emission spectrometer (ICP-OES; Avio 200, PerkinElmer, USA). X-ray photoelectron spectroscopy (XPS) was carried out with an X-ray photoelectron spectrometer (K-Alpha, Thermo Scientific, USA). The UV-vis diffuse reflectance spectra (DRS) data were recorded using a UV-vis spectrophotometer (UV-3600i Plus, Shimadzu, Japan). Fluorescence lifetimes and apparent quantum efficiency (AQE) were determined using a steady-state/transient fluorescence spectrometer (FLS980, Edinburgh Instruments, UK) with an excitation laser

of 375 nm. Electron paramagnetic resonance (EPR) spectra were detected with an electron paramagnetic resonance spectrometer (Bruker A300, Bruker Corporation, Germany). Photoelectrochemical and the electrochemical impedance spectrum (EIS) measurements were conducted in a traditional three-electrode system using an electrochemical workstation (CHI 760E, Shanghai Chenhua, China), as described in our previous study.<sup>28</sup>

### Photocatalytic N<sub>2</sub> reduction evaluation

Photocatalytic nitrogen reduction reactions were conducted in a quartz reactor under the illumination of a 300 W xenon lamp with 420 nm cutoff filter. The sample (30 mg) was dispersed in 60 mL of ultrapure water (multiple distillations to remove NH<sub>4</sub><sup>+</sup>) at 25 °C. Before irradiation, the mixture was stirred in the dark under high-purity nitrogen (purity ≥99.999%, 100 mL min<sup>-1</sup>) for 60 min to saturate the suspension with nitrogen. The lamp was then turned on, and 3 mL of the suspension was collected every 30 min for 2 h. The concentration of NH<sub>4</sub><sup>+</sup> was determined by Nessler's reagent spectrophotometry (UH4150, Hitachi, Japan) and ion chromatography (Dionex Aquion RFIC, ThermoFisher, USA) equipped with a cation detector. An isotopic labeling experiment was conducted using <sup>15</sup>N isotope-labeled N<sub>2</sub> by the photocatalytic nitrogen reduction reaction process. A nuclear magnetic resonance spectrometer (NMR, AVANCE III HD 500 M, Bruker, USA) was used to detect the characteristic peaks of <sup>15</sup>NH<sub>4</sub><sup>+</sup>, and dimethyl sulfoxide was used to calibrate the chemical shifts of the <sup>1</sup>H NMR spectra. Besides, the pH of the aqueous solution was adjusted using 1 M H<sub>2</sub>SO<sub>4</sub> or 1 M NaOH to explore the effect of pH on N<sub>2</sub> reduction activity.

### Computational details

All calculations for BiVO<sub>4</sub> and FeBiVO<sub>4</sub> models were conducted within the spin-polarized DFT framework, as implemented in the DMol3 code available in Materials Studio.<sup>29</sup> The generalized gradient approximation (GGA) in the form of the Perdew-Wang (PW91) functional<sup>30,31</sup> was used to describe the exchange-correlation term. Core electrons of the transition metal were replaced by effective nuclear potential pseudopotential (ECP), and the valence electron wave function set was chosen as double-numerical polarization (DNP). All geometries were fully optimized until the energy tolerance reached less than  $2.0 \times 10^{-5}$  Ha, the maximum displacement was less than  $5.0 \times 10^{-3}$  Å, and the convergence of force on each atom was  $4.0 \times 10^{-1}$  Ha Å<sup>-1</sup>. The convergence criterion of the self-consistent field (SCF) is  $10^{-6}$  Ha. Adsorption energy (E<sub>b</sub>) is defined as the difference between the total energy of the adsorption systems (E<sub>t</sub>), and the sum of the calculated surface energy (E<sub>s</sub>) and N<sub>2</sub> energy (E<sub>N<sub>2</sub></sub>):<sup>32</sup>

$$E_b = E_t - (E_{N_2} + E_s) \quad (1)$$

The Gibbs free energy changes for each N<sub>2</sub> reduction step were calculated as follows:<sup>33</sup>

$$\Delta G = \Delta ZPE + \Delta E - T\Delta S \quad (2)$$

where  $\Delta ZPE$  and  $\Delta E$  are the calculated zero-point energy difference and total energy difference, respectively, and  $T\Delta S$  is the entropy contribution at 298.15 K.

## Results and discussion

### Structure and chemical state

The XRD patterns (Fig. 1) show that the diffraction peaks of all samples align well with the standard card of BiVO<sub>4</sub> (JCPDS #14-0688), indicating the successful realization of the monoclinic phase of BiVO<sub>4</sub>.<sup>34,35</sup> For single Fe-doped samples (FeBiVO<sub>4</sub>), no Fe-related crystalline phase is observed due to the low Fe content.<sup>36</sup> In addition, since Fe<sup>3+</sup>/Fe<sup>2+</sup> ion radius (67 pm/78 pm) is less than Bi<sup>3+</sup> ion radius (103 pm), the lattice parameters of BiVO<sub>4</sub> decrease after Fe<sup>3+</sup>/Fe<sup>2+</sup> replaces Bi<sup>3+</sup> (Table S1†), indicating that Fe ions partially replace Bi<sup>3+</sup> and enter into the BiVO<sub>4</sub> lattice.<sup>13</sup> For the BP-decorated samples, two new peaks appear at  $2\theta = 16.8^\circ$  and  $52.3^\circ$  (lattice planes of (0 2 0) and (0 6 0)) and an overlapping peak appears at  $2\theta = 34.2^\circ$  (lattice plane of (0 4 0)) due to the introduction of black phosphorus (BP) (JCPDS #67-1957).<sup>37</sup> The XRD intensities of BP peaks increase with the increasing amount of BP.

Fig. S1a-d† shows the SEM images of BiVO<sub>4</sub>, FeBiVO<sub>4</sub>, FeBiVO<sub>4</sub>-0.05BP, and BiVO<sub>4</sub>-0.05BP samples. It is evident that the ternary FeBiVO<sub>4</sub>-0.05BP photocatalyst consists of FeBiVO<sub>4</sub> nanoparticles and BP nanosheets, and Fe doping has no effect on the morphology of the catalysts. Additionally, the thickness of the 2D BP nanosheets is about 4 nm, while the thickness of FeBiVO<sub>4</sub> particles is larger than 100 nm, as shown in Fig. 2. The ICP-OES analysis (Table S2†) shows that the real molarity of Fe and mass concentration of P is roughly consistent with the theoretical concentrations. In particular, the addition of BP nanosheets is conducive to increasing the BET surface areas of the catalytic system (Table S1†).

Fig. 1 XRD patterns of different samples: BiVO<sub>4</sub>, FeBiVO<sub>4</sub>, BiVO<sub>4</sub>-0.05BP, FeBiVO<sub>4</sub>-0.05BP, FeBiVO<sub>4</sub>-0.02BP and FeBiVO<sub>4</sub>-0.10BP.

Fig. 2 AFM images of  $\text{FeBiVO}_4\text{-}0.05\text{BP}$  (left) and the corresponding thickness distribution (right).

High-resolution TEM, high-angle annular dark-field scanning TEM (HADDF-STEM), and energy dispersive spectrometer (EDS) mapping analysis were carried out to reveal the heterogeneous structure and elemental distribution in the  $\text{FeBiVO}_4\text{-}0.05\text{BP}$  samples (Fig. 3). The high-resolution TEM of  $\text{FeBiVO}_4\text{-}0.05\text{BP}$  (Fig. 3b) shows interplanar spacings of 0.29, 0.47, and 0.31 nm, which matched with the (2 0 0), (1 1 0) and (−1 2 1) planes of the monoclinic  $\text{BiVO}_4$ , respectively. Fig. 3c–i displays the HADDF-STEM image and the corresponding EDS mapping. The result shows a uniform distribution of Bi, O, V, Fe, and P elements in the  $\text{FeBiVO}_4\text{-}0.05\text{BP}$  sample, indicating that the Fe ions and BP nanosheets are evenly introduced into the catalytic system. These results fully confirm the successful formation of homogeneous-doped  $\text{FeBiVO}_4\text{-}0.05\text{BP}$  heterojunction composites.

The XPS analysis provides information about the valence states and elemental composition of the  $\text{BiVO}_4$  and  $\text{FeBiVO}_4\text{-}0.05\text{BP}$  samples,<sup>38</sup> as shown in Fig. 4. The O XPS spectra (Fig. 4a) have two peaks at 530.2 and 532.9 eV, attributed to bound oxygen ( $\text{O}_\text{L}$ , Bi–O, and V–O) and adsorbed oxygen ( $\text{O}_\text{OH}$ ) in  $\text{BiVO}_4$ , respectively.<sup>39</sup> The O peak at 531.8 eV was attributed to the increased adsorption capacity of the catalyst surface by the introduction of oxygen vacancies ( $\text{O}_\text{V}$ ) in  $\text{FeBiVO}_4\text{-}0.05\text{BP}$ ,<sup>40</sup> indicating the oxygen vacancy formation due to Fe ion doping. Meanwhile, oxygen vacancies in  $\text{BiVO}_4$  usually accompany the coupling formation of  $\text{V}^{4+}$  species.<sup>41</sup> Fig. 4b shows the XPS spectra of V 2p, which contains two peaks with binding energies of 524.4 and 516.9 eV, respectively, ascribed to V 2p<sub>1/2</sub> and V 2p<sub>3/2</sub> of the  $\text{V}^{5+}$  cation. After Fe ion doping, a new peak at 515.0 eV can be assigned to the  $\text{V}^{4+}$  cation,<sup>42</sup> which confirms the formation of a couple of oxygen vacancies and  $\text{V}^{4+}$  species in Fe-doped  $\text{BiVO}_4$ . Furthermore, the XPS spectra of Bi are shifted by doping Fe ions, demonstrating that Fe is involved in the bonding of the  $\text{BiVO}_4$  lattice<sup>43</sup> (Fig. S2†). Additionally, after Fe ions were introduced into the catalyst system, XPS peaks of

the  $\text{Fe}^{3+}/\text{Fe}^{2+}$  couple could be observed in Fig. 4c. In detail, the binding energies of 728.8 eV (2p<sub>1/2</sub>) and 713.5 eV (2p<sub>3/2</sub>) are the peaks of the  $\text{Fe}^{3+}$  cation, while the binding energies of 724.0 eV (2p<sub>1/2</sub>) and 710.4 eV (2p<sub>3/2</sub>) belong to the  $\text{Fe}^{2+}$  cation. These results show that  $\text{V}^{5+}/\text{V}^{4+}$  and  $\text{Fe}^{3+}/\text{Fe}^{2+}$  redox couples are successfully introduced into  $\text{BiVO}_4$  crystals by doping Fe ions. As for the XPS spectra of P 2p in  $\text{FeBiVO}_4\text{-}0.05\text{BP}$ , Fig. 4d displays two fitted peaks at 129.6 and 128.9 eV, respectively, ascribed to P 2p<sub>1/2</sub> and P 2p<sub>3/2</sub> of P<sup>0</sup>.<sup>44</sup> Moreover, a stronger  $\text{PO}_x$  peak is found in the XPS spectrum of the  $\text{FeBiVO}_4\text{-}0.05\text{BP}$  sample, which is related to the oxidation of BP in  $\text{FeBiVO}_4\text{-}0.05\text{BP}$  samples. An oxidation process is inevitable in BP-based materials.<sup>45</sup>

#### Evaluation of the photocatalytic nitrogen reduction performance

The photocatalytic nitrogen reduction performance of the prepared samples under visible light is evaluated without an organic scavenger, as shown in Fig. 5a. The concentrations of  $\text{N}_2\text{H}_4$  and  $\text{NH}_3$  in the reaction solutions were simultaneously detected, but no  $\text{N}_2\text{H}_4$  was observed. After 120 min of visible light irradiation, the  $\text{NH}_3$  yield of pure  $\text{BiVO}_4$  was  $49.45 \mu\text{mol g}^{-1} \text{h}^{-1}$ . As expected, both Fe doping and BP decoration significantly enhanced the  $\text{NH}_3$  yield of  $\text{BiVO}_4$ . The  $\text{NH}_3$  yield of  $\text{FeBiVO}_4\text{-}0.05\text{BP}$  is  $337.9 \mu\text{mol g}^{-1} \text{h}^{-1}$ , which is 6.83 times that of  $\text{BiVO}_4$ . The results obtained by cationic exchange chromatography are almost identical (Fig. S3†). Compared to other photocatalysts, the  $\text{FeBiVO}_4\text{-}0.05\text{BP}$  photocatalyst exhibited excellent nitrogen reduction activity (Table S3†).  $\text{NH}_3$  production of  $\text{FeBiVO}_4\text{-}0.10\text{BP}$  ( $265.9 \mu\text{mol g}^{-1} \text{h}^{-1}$ ) decreased when the concentration of BP decoration was increased to 10%, possibly due to excessive BP being the recombination centers of photoinduced carriers. Moreover, the  $\text{FeBiVO}_4\text{-}0.05\text{BP}$  photocatalytic system did not produce  $\text{NH}_3$  when only high-purity Ar flows continuously, which means that  $\text{N}_2$  is the

**Fig. 3** (a) TEM and (b) High-resolution TEM images of  $\text{FeBiVO}_4\text{-}0.05\text{BP}$ ; (c) HAADF-STEM image and corresponding EDS mapping: (d) Bi, (e) O, (f) V, (h) Fe, (i) P.

only nitrogen source to produce  $\text{NH}_3$ . The photocatalytic nitrogen reduction stability of  $\text{FeBiVO}_4\text{-}0.05\text{BP}$  is evaluated by seven cycles, as shown in Fig. 5b. The results indicate that the nitrogen reduction activity and structure of  $\text{FeBiVO}_4\text{-}0.05\text{BP}$  are relatively stable in multiple cycles (Fig. S4†).

To further confirm the accuracy of  $\text{NH}_3$  generation from  $\text{N}_2$ , an isotope labeling test was performed to examine the reaction solution of  $\text{FeBiVO}_4\text{-}0.05\text{BP}$  (Fig. 5c). Generally, the  $^1\text{H}$  NMR spectra of the  $^{15}\text{NH}_4^+$  standard sample displays a pair of coupled peaks.<sup>46</sup> The characteristic peaks of  $^{15}\text{NH}_4^+$  are detected using the  $^1\text{H}$  NMR spectrum when the feeding gas is  $^{15}\text{N}_2$ , indicating that the N element of  $\text{NH}_3$  comes from the feed gas  $\text{N}_2$ .

Fig. 5d shows the effect of pH values of the reaction solution on  $\text{NH}_3$  yield investigated. When  $\text{pH} = 7$ , the reduction

performance of  $\text{N}_2$  is the best, while the increase or decrease of pH value will lead to the decrease of photocatalytic  $\text{N}_2$  reduction activities. Under acidic conditions, an increase in  $\text{H}^+$  concentration leads to decreased water oxidation. However, under alkaline conditions, although the oxidation of water was improved, the produced  $\text{NH}_4^+$  was being oxidized faster, thus reducing the production of  $\text{NH}_3$ .<sup>47</sup>

#### Mechanism of improved photocatalytic activity

To explore the mechanism of Fe doping or 2D BP decoration in regulating the nitrogen reduction reaction one by one, first, theoretical calculations were conducted on the mechanism of Fe doping on  $\text{BiVO}_4$  (Fig. 6). There are three main reaction pathways in the process of photocatalytic  $\text{NH}_3$  synthesis,

**Fig. 4** High-resolution XPS of (a) O 1s and (b) V 2p for  $\text{BiVO}_4$  and  $\text{FeBiVO}_4\text{-}0.05\text{BP}$ , high-resolution XPS of (c) Fe 2p and (d) P 2p for  $\text{FeBiVO}_4\text{-}0.05\text{BP}$ .

**Fig. 5** (a) Photocatalytic  $\text{N}_2$  reduction of  $\text{BiVO}_4$ ,  $\text{FeBiVO}_4$ ,  $\text{BiVO}_4\text{-}0.05\text{BP}$ ,  $\text{FeBiVO}_4\text{-}0.05\text{BP}$ ,  $\text{FeBiVO}_4\text{-}0.02\text{BP}$  and  $\text{FeBiVO}_4\text{-}0.10\text{BP}$  under visible light irradiation. (b) Stability test for the nitrogen reduction of the  $\text{FeBiVO}_4\text{-}0.05\text{BP}$  photocatalyst. (c)  ${}^1\text{H}$  NMR spectra qualitative isotope labeling test of  $\text{FeBiVO}_4\text{-}0.05\text{BP}$ . namely the distal reaction pathway, alternate reaction pathway, and enzymatic reaction pathway.<sup>48</sup> The distal mechanism was considered the most potential reaction pathway in the  $\text{BiVO}_4$

system.<sup>18</sup> The optimized structures of the reaction intermediate for nitrogen reduction over  $\text{BiVO}_4$  and  $\text{FeBiVO}_4$  by a distal mechanism are presented in Fig. 6a and b. Moreover, it has

**Fig. 6** Optimized structures of reaction intermediates in a distal mechanism: (a)  $\text{BiVO}_4$  and (b)  $\text{FeBiVO}_4$ ; (c) Gibbs free energy profiles of nitrogen reduction over  $\text{BiVO}_4$  and  $\text{FeBiVO}_4$  catalysts by a distal mechanism.

been reported that  $\text{N}_2$  molecules can only be adsorbed on the (0 4 0) plane of  $\text{BiVO}_4$ .<sup>18</sup> Herein, we focus on the nitrogen reduction reaction occurring on the (0 4 0) plane of  $\text{BiVO}_4$  and  $\text{FeBiVO}_4$ , respectively. When  $\text{BiVO}_4$  is involved in the nitrogen reduction reaction, the adsorption and reduction of  $\text{N}_2$  molecules occur at the Bi sites, while the V sites are almost not directly involved. During the nitrogen reduction reaction of  $\text{FeBiVO}_4$ , the adsorption and reduction of  $\text{N}_2$  at the active sites are mainly related to the V sites, which may be due to the bionic effect of FeV formed by Fe doping. This effect can promote the adsorption and activation of  $\text{N}_2$  molecules, and the formed  $\text{V}^{5+}/\text{V}^{4+}$  and  $\text{Fe}^{3+}/\text{Fe}^{2+}$  redox couples can promote the continuous transfer of multiple electrons/protons (Fig. S5†).

Fig. 6c shows the Gibbs free energy profiles of nitrogen reduction over  $\text{BiVO}_4$  and  $\text{FeBiVO}_4$  catalysts by a distal mechanism. For the nitrogen reduction reaction of  $\text{BiVO}_4$ , three steps are involved in the increase of the Gibbs free energy. The first step is the hydrogenation of the adsorbed  $\text{N}_2$  molecules (eqn (4)), increasing the free energy by 4.76 eV. The second step is the release of the first  $\text{NH}_3$  (eqn (7)), and the free energy is increased by 3.68 eV. The third step is the release of the second  $\text{NH}_3$  (eqn (10)), and the free energy is increased by 3.87 eV. Except for these three steps, the remaining nitrogen reduction processes are exergonic. It can be found that the rate-determining step of the nitrogen reduction reaction by  $\text{BiVO}_4$  is the generation of the  $+\text{NNH}$  intermediate (eqn (4)). Although the increase in Gibbs free energy also has three steps for the nitrogen reduction reaction of  $\text{FeBiVO}_4$ , the rate-determining step changed to the generation of the first  $\text{NH}_3$  (eqn (7)), and it also has a lower  $\Delta G$  value of 3.50 eV than that of  $\text{BiVO}_4$  (3.68 eV). The DFT results showed that the design of the bionic FeV made the hydrogenation of  $\text{N}_2$  (eqn (4)) no longer a decisive step in the catalytic system, indicating that the construction of FeV active centers is conducive to the activation and hydrogenation of  $\text{N}_2$  molecules, thus effectively accelerating the conversion of  $\text{N}_2$  to  $\text{NH}_3$ . Each basic reaction step can be written as follows. The corresponding equations for the change in Gibbs free energy are as follows.

Subsequently, the above calculation results were verified experimentally, and the synergistic effect of Fe doping and 2D BP decoration was further explored. Fe doping and BP decoration greatly improved the photocatalytic activity of  $\text{BiVO}_4$ . This improvement is usually due to the increased specific surface area, enhanced charge separation, and improved light absorption. As mentioned above, Fe doping hardly affects the specific surface area of the  $\text{BiVO}_4$  catalysts, while BP can significantly increase the specific surface area of the  $\text{BiVO}_4$  and  $\text{FeBiVO}_4$  catalysts by promoting the dispersion of the  $\text{BiVO}_4$  nanoparticles (Fig. S1 and Table S2†), thus increasing the number of active sites required for the reaction.

More importantly, photocurrent response experiments were performed and time-resolved photoluminescence (PL) spectra were obtained to evaluate the photoinduced charge carrier generation, separation, and transfer efficiency in the  $\text{BiVO}_4$  and  $\text{FeBiVO}_4$ -0.05BP photocatalysts.<sup>49</sup> As shown in Fig. 7a, the

photocurrent intensities of Fe- or V-modified samples are higher than that of pure  $\text{BiVO}_4$ , and  $\text{FeBiVO}_4\text{-}0.05\text{BP}$  showed the strongest photocurrent intensity, indicating that both Fe doping and BP decoration can greatly promote the generation and transfer of photoinduced charge carriers. Furthermore, electrochemical impedance spectroscopy (EIS) was applied to study the influence of the Fe doping and BP decoration on the impedance property of  $\text{BiVO}_4$  (Fig. 7b). The  $\text{FeBiVO}_4\text{-}0.05\text{BP}$  curve corresponds to the smallest arc radius, which indicates that the photo-generated carriers are subjected to the least resistance during the transfer process. Compared with BP decoration, the effect of Fe doping on impedance is significantly greater, indicating that Fe doping may be the direct cause of promoting continuous transfer of multiple electrons/protons by the formed  $\text{V}^{5+}/\text{V}^{4+}$  and  $\text{Fe}^{3+}/\text{Fe}^{2+}$ .

As illustrated in Fig. S6,<sup>†</sup> the formula of  $\tau_{\text{avg.}} = \frac{\sum A_i \tau_i^2}{\sum A_i \tau_i}$  is used to calculate the average fluorescence lifetime, where the decay in fluorescence intensity ( $I$ ) with time ( $t$ ) is fitted by a phenomenological double exponential:<sup>50</sup>

$$I = A_1 \exp\left(-\frac{t - t_0}{\tau_1}\right) + A_2 \exp\left(-\frac{t - t_0}{\tau_2}\right) \quad (11)$$

The fluorescence life of  $\text{FeBiVO}_4\text{-}0.05\text{BP}$  (8.29 ns) is about 3.5 times that of  $\text{BiVO}_4$  (2.37 ns). In addition, the apparent quantum efficiency (AQE) of the  $\text{BiVO}_4$  and  $\text{FeBiVO}_4\text{-}0.05\text{BP}$  samples is measured under 420 and 460 nm monochromatic

light with intensities of 4.72 and 5.65  $\text{mW cm}^{-2}$ , respectively. The AQE is calculated by the following formula:<sup>51</sup>

$$\text{AQE} = \frac{N_{\text{NH}_3}}{N_{\text{P}}} = \frac{6 \times \text{the number of evolved } \text{NH}_3 \text{ molecules}}{\text{the number of incident photons}} \times 100\% \quad (12)$$

The  $\text{NH}_3$  yields of  $\text{BiVO}_4$  and  $\text{FeBiVO}_4\text{-}0.05\text{BP}$  were measured after 2 h of light irradiation. The AQE of  $\text{FeBiVO}_4\text{-}0.05\text{BP}$  reached 2.53% at 420 nm and 1.22% at 460 nm, respectively, which are significantly higher than that of  $\text{BiVO}_4$  (0.85% at 420 nm and 0.52% at 460 nm).

These results demonstrate that the inbuilt bionic FeV cofactor not only adsorbs and activates  $\text{N}_2$  molecules but also promotes the electron transfer between redox couples ( $\text{V}^{5+}/\text{V}^{4+}$  &  $\text{Fe}^{3+}/\text{Fe}^{2+}$ ) and  $\text{N}_2$ , thus improving the efficiency of carrier separation. 2D BP decoration not only increases the active sites of the nitrogen reduction reaction but also contributes to accelerating the electron transport of the catalytic system.

Electron paramagnetic resonance (EPR) was used to detect the sample's structural characteristics and oxygen vacancies (OV). As shown in Fig. 7c, almost no signal is observed for  $\text{BiVO}_4$  at  $g = 2.001$ , while two strong characteristic peaks appeared for both  $\text{FeBiVO}_4$  and  $\text{FeBiVO}_4\text{-}0.05\text{BP}$ , which are typical of oxygen vacancies.<sup>52</sup> It is further confirmed that the catalytic system generated coupled  $\text{V}^{4+}$  and  $\text{O}_v$  after the Fe doping, which is consistent with the results of XPS. The appearance of  $\text{O}_v$  can change the electronic structure of the semiconductor and generate subbands.<sup>53</sup> XPS valence band

Fig. 7 (a) Photocurrent response and (b) electrochemical impedance spectroscopy (EIS) tests of  $\text{BiVO}_4$ ,  $\text{FeBiVO}_4$ ,  $\text{BiVO}_4\text{-}0.05\text{BP}$  and  $\text{FeBiVO}_4\text{-}0.05\text{BP}$ ; (c) EPR spectra and (d) XPS valence state spectra of  $\text{BiVO}_4$ ,  $\text{FeBiVO}_4$  and  $\text{FeBiVO}_4\text{-}0.05\text{BP}$ .

Fig. 8 Schematic diagram of the nitrogen reduction mechanisms over the FeBiVO<sub>4</sub>-0.05BP photocatalyst.

spectra are used to characterize the approximate valence band (VB) location in the photocatalysts, as shown in Fig. 7d. The VB values of BiVO<sub>4</sub>, FeBiVO<sub>4</sub>, and FeBiVO<sub>4</sub>-0.05BP are almost the same, indicating that Fe doping and BP decoration had little effect on the VB of BiVO<sub>4</sub>. The DRS results show that Fe doping has the most obvious effect on the band gap (Fig. S7†), indicating that the O<sub>V</sub> caused by Fe doping moves down the conduction band (CB) of the semiconductor catalytic system to a certain extent, thus leading to a decrease in the band gap when the VB value remains unchanged.

Based on the above results, the internal mechanisms of Fe doping and 2D BP decoration in regulating photocatalytic nitrogen reduction are summarized, as shown in Fig. 8. Fe doping induces lattice distortion to form the Fe<sup>3+</sup>/Fe<sup>2+</sup> and V<sup>5+</sup>/V<sup>4+</sup> redox couples (“FeV-cofactor”), which not only adsorbs and activates N<sub>2</sub> molecules but also promotes the electron transfer between “FeV-cofactor” and N<sub>2</sub>; appropriate 2D BP decoration can not only increase the active sites of the reaction but also facilitate the rapid electron transfer in the process of nitrogen reduction. In classical photocatalysis, electrons on VB are excited and transferred to the conduction band (CB) to obtain photoinduced electrons (e<sub>CB</sub><sup>-</sup>) and form holes in VB (h<sub>VB</sub><sup>+</sup>), as shown in eqn (13). N<sub>2</sub> molecules are adsorbed onto the V sites of the (0 4 0) plane in BiVO<sub>4</sub>, then capture e<sub>CB</sub><sup>-</sup> and combine with the V-O bond to form a stable adsorption structure (V<sup>4+</sup>@NN), as shown in eqn (14). At the same time, Fe<sup>3+</sup> captures e<sub>CB</sub><sup>-</sup> to form Fe<sup>2+</sup> (eqn (15)). With the assistance of BP, the reductive V<sup>4+</sup>@NN and the equally reductive Fe<sup>2+</sup> react with the free H<sup>+</sup> to form NH<sub>3</sub> (eqn (16)). At this point, h<sub>VB</sub><sup>+</sup> can react directly with H<sub>2</sub>O molecules to form O<sub>2</sub> (eqn (17)).

Moreover, the formation of O<sub>V</sub> can form defect levels below the CB, which can accommodate low-energy electrons excited by low-energy light;<sup>54</sup> and e<sub>CB</sub><sup>-</sup> in the CB can also be further transferred to the O<sub>V</sub> levels, significantly inhibiting the recombination of charge carriers. Furthermore, with the introduction of O<sub>V</sub>, V atoms with lower coordination and high spin polarization become more favorable active sites.<sup>55</sup>

## Conclusion

In summary, a novel bionic “FeV-cofactor” system for photocatalytic nitrogen reduction was designed and prepared for the first time, using Fe-doped BiVO<sub>4</sub> that is decorated with 2D BP (FeBiVO<sub>4</sub>-0.05BP). DFT calculations show that N<sub>2</sub> molecules can be adsorbed and activated by Fe doping, forming the in-built bionic “FeV-cofactor”. The experimental results further confirms that the bionic “FeV-cofactor” system enhances electron transfer between redox couples (V<sup>5+</sup>/V<sup>4+</sup> & Fe<sup>3+</sup>/Fe<sup>2+</sup>) and N<sub>2</sub>, thus improving the carrier separation efficiency. Oxygen vacancies coupled with V<sup>4+</sup> ions also contribute to increasing light absorption. 2D BP decoration not only increases the active sites of the nitrogen reduction reaction but also contributes to accelerating the electron transport within the catalytic system. Thus, the FeBiVO<sub>4</sub>-0.05BP catalyst exhibits superior photocatalytic nitrogen reduction activity with an NH<sub>3</sub> yield of 337.9 μmol g<sup>-1</sup> h<sup>-1</sup> (6.83 times that of BiVO<sub>4</sub>), making it one of the best nitrogen-fixing materials among oxide-based photocatalysts.
