A cobalt(II) iminoiodane complex and its scandium adduct: mechanistic promiscuity in hydrogen atom abstraction reactions†

Subrata Kundu,^a Petko Chernev,^b Xenia Engelmann,^a Chan Siu Chung,^c Holger Dau,^b Eckhard Bill,^d Jason England,^{*c} Wonwoo Nam^{*e} and Kallol Ray^{*a}

In addition to oxometal $[M^{n+}=O]$ and imidometal $[M^{n+}=NR]$ units, transient metal–iodosylarene $[M^{(n-2)+}-O=IPh]$ and metal–iminoiodane $[M^{(n-2)+}-N(R)=IPh]$ adducts are often invoked as a possible “second oxidant” responsible for the oxo and imido group transfer reactivity. Although a few metal–iodosylarene adducts have been recently isolated and/or spectroscopically characterized, metal–iminoiodane adducts have remained elusive. Herein, we provide UV-Vis, EPR, NMR, XAS and DFT evidence supporting the formation of a metal–iminoiodane complex **2** and its scandium adduct **2-Sc**. **2** and **2-Sc** are reactive toward substrates in the hydrogen-atom and nitrene transfer reactions, which confirm their potential as active oxidants in metal-catalyzed oxidative transformations. Oxidation of *para*-substituted 2,6-di-*tert*-butylphenols by **2** and **2-Sc** can occur by both coupled and uncoupled proton and electron transfer mechanisms; the exact mechanism depends on the nature of the *para* substituent.

Iodosobenzene ($PhI=O$) and iminoiodanes ($PhI=NR$) are an important class of group transfer reagents in organic synthesis, and they are often used in conjunction with transition metal-based catalysts.¹ High-valent oxometal $[M^{n+}=O]$ and imidometal $[M^{n+}=NR]$ units are generally accepted to be key reactive intermediates in these reactions.² However, transient metal–iodosylarene $[M^{(n-2)+}-O=IPh]$ ³ and metal–iminoiodane $[M^{(n-2)+}-N(R)=IPh]$ ⁴ adducts have also been suggested as a possible “second oxidant” responsible for this oxo and imido

group transfer reactivity. Nam *et al.* reported the first isolation and spectroscopic characterization of an iodosobenzene adduct, namely $[(porph)Fe^{III}(OIPh)]^+$, from the reaction of $[(porph^+)Fe^{IV}O]^+$ with iodobenzene.^{3c} Very recently, McKenzie *et al.* provided the molecular structure of a non-heme iron(III) iodosylarene adduct by X-ray crystallography.^{3d} Fujii *et al.*^{3e,f} also reported structural and spectroscopic evidence in support of bis(iodosylarene) coordination to a manganese(IV)–salen center. Notably, the aforementioned isolated $[M^{(n-2)+}-O=IPh]$ adducts were all found to be reactive toward substrates in both hydrogen- and oxygen-atom transfer reactions, which confirms their potential as active oxidants in metal-catalyzed oxidative transformations.³ In contrast, isoelectronic $[M^{(n-2)+}-N(R)=IPh]$ complexes have remained elusive, and their presence as transient reactive intermediates has been forwarded on the basis of labelling experiments alone.^{4a}

Herein, we describe the spectroscopic characterization of a novel $[(TMG_3tren)Co^{II}-(^sPhINTs)]^{2+}$ (**2**) complex [$^sPhINTs = \{N-(p\text{-toluenesulfonyl})imino\}(2\text{-tert-butylsulfonyl})phenyliodinane$;⁵ $TMG_3tren = \text{tris}\{N\text{-tetramethylguanidyl}\}ethylamine$] and its scandium adduct $[(TMG_3tren)Co^{II}-^sPhINTs(Sc(OTf)_3)]^{2+}$ (**2-Sc**, $OTf = CF_3SO_2^-$), which are able to oxidize the C–H and O–H bonds of a variety of substrates. Additionally, we demonstrate that the presence of Sc^{3+} in **2-Sc** initiates a two-step reaction mechanism for the oxidation of benzyl alcohol ($PhCH_2OH$), involving a $[Co^{II}-(^sPhINTs) \cdots Sc^{3+} \cdots O(H)-CH_2Ph]$ association event prior to C

Fig. 1 Main: Electronic spectra of **1** (solid trace), ⁵PhINTs (dash-dotted trace), **2** (dashed trace), and **2-Sc** (dotted trace) in acetone at $-40\text{ }^{\circ}\text{C}$. Inset: Plot of the absorbance of the 420 nm band of **2** against the equivalents of ⁵PhINTs added to **1**. Notably, **2** and **2-Sc** can also be generated in CH_2Cl_2 with λ_{max} [ϵ_{max}] values identical to that observed in acetone.

inset) show that addition of only 1 equiv. ⁵PhINTs to **1** is necessary to maximize the yield of **2**. Similarly, the $^1\text{H-NMR}$ spectrum of **2** is distinct from that of **1** + free ⁵PhINTs (Fig. S2 and S3[†]), and does not show the presence of any unreacted starting materials in significant amounts. Moreover, in the $^1\text{H-NMR}$ spectrum of **2** the complete set of signals expected for ⁵PhINTs are observed (Fig. S3[†]), which are broadened and shifted to slightly higher fields relative to free ⁵PhINTs; this can be attributed to binding to the paramagnetic cobalt centre.

Upon addition of scandium triflate ($\text{Sc}(\text{OTf})_3$) at $-40\text{ }^{\circ}\text{C}$, **2** is instantaneously converted to a new species **2-Sc** (λ_{max} [ϵ_{max}] = 450 nm [$1350\text{ M}^{-1}\text{ cm}^{-1}$] and 885 nm [$180\text{ M}^{-1}\text{ cm}^{-1}$]) (Fig. 1). As was the case for ⁵PhINTs, only 1 equiv. Sc^{3+} is required for complete conversion of **2** to **2-Sc** (Fig. S4[†]). Notably, complex **1** can also be converted directly to **2-Sc** by reacting with ⁵PhINTs in the presence of 1 equiv. $\text{Sc}(\text{OTf})_3$. Both **2** and **2-Sc** are meta-stable intermediates with half-lives ($t_{1/2}$) of 3600 and 720 seconds, respectively, at $25\text{ }^{\circ}\text{C}$.

The electronic structures of **2** and **2-Sc** were probed by EPR spectroscopy. Surprisingly, in spite of the significant differences in their UV-Vis spectra, the X-band EPR spectra of **2** and **2-Sc** (Fig. S5[†]) exhibit identical axial $S = 3/2$ signals, with effective g values of $g^{\perp} = 4.40$ and $g^{\parallel} = 2.09$ that are strikingly similar to the previously reported⁶ axial EPR signals of **1**. Furthermore, the EPR spectra of the series of $[(\text{TMG}_3\text{tren})\text{Co}^{\text{II}}\text{X}]^+$ ($\text{X} = \text{OTf}, \text{Cl}, \text{SCN}, \text{N}_3, \text{CH}_3\text{COO}, \text{CN}$) complexes all exhibit axial $S = 3/2$ signals identical to **2**, with effective g values of $g^{\perp} = 4.40$ and $g^{\parallel} = 2.09$, even though their UV-Vis spectra are distinct from one another (Fig. S6[†]). This shows that the EPR parameters of the $\{(\text{TMG}_3\text{tren})\text{Co}^{\text{II}}\}$ moiety are effectively independent of the nature of the fifth ligand, and appear to be dictated solely by the strong binding of the TMG_3tren ligand to the Co^{II} ion. The EPR parameters change only when the formal oxidation state of cobalt is altered. For example, a

rhombic EPR spectrum ($E/D = 0.15 \pm 0.01$) with split effective $g^{\perp} = 5.60, 3.60$, and $g^{\parallel} = 1.96$ was observed for the unusual $\{(\text{TMG}_3\text{tren})\text{Co}^{\text{IV}}\text{-O-Sc}^{3+}\}$ (**3-Sc**) core containing a cobalt center with a formal oxidation state of +4.⁶ Taken together, the near-identical EPR spectra of **2**, **2-Sc**, and **1** indicate that the cobalt centers in **2** and **2-Sc** retain the +2 oxidation state of **1**.

2 and **2-Sc** were further characterized by X-ray absorption spectroscopy (XAS). The positions of the Co K-edges of these complexes do not differ from that of **1** (Fig. S7[†]), which indicates that the reaction of **1** with ⁵PhINTs does not cause a change in the Co^{II} oxidation state. This result is in agreement with our EPR study

Scheme 1 Products from reactions of **1** with $^5\text{PhINTs}$, in the presence and absence of Sc^{3+} ions. The DFT calculated possible structures of **2** and their relative energies in the $S = 3/2$ ground state are shown in the inset. Color code: C, grey; O, red; N, blue; Co, brown; sulfur, yellow; iodine, violet.

mass spectrum (ESI-MS; Fig. S9[†]) of both **2** and **2-Sc** exhibits a prominent peak at $m/z = 496.15$, with a mass and isotope distribution pattern corresponding to $[(\text{TMG}_3\text{tren})\text{Co}^{\text{II}}-(^5\text{PhINTs})]^{2+}$.

DFT calculations were also performed in order to obtain further insights into the electronic and geometric structures of **2**.⁷ The binding of $^5\text{PhINTs}$ to the cobalt center in **2** can in principle occur either *via* the sulfonamide group (O-bound or N-bound) or alternatively *via* one of the O-atoms of the sulfone group (Scheme 1 and Table S4[†]). The most stable structure of the experimentally observed spin-quartet ground ($S = 3/2$) state was calculated to contain the O-bound sulfonamide binding mode of $^5\text{PhINTs}$ (Scheme 1, inset), with the respective energies (Table S5[†]) of the geometry optimized structures of

the more sterically disfavoured N-bound sulfonamide and O-bound sulfone isomers being higher by 15.3 and 26.9 kcal mol⁻¹ respectively. Consistent with this conclusion, the DFT calculated average Co–N/O distance of 2.10 Å (corresponding to four N-donors of TMG_3tren and one O-donor of $^5\text{PhINTs}$) in an $S = 3/2$ O-bound sulfonamide $[(\text{TMG}_3\text{tren})\text{Co}^{\text{II}}-(^5\text{PhINTs})]^{2+}$ complex (Tables S1 and S4[†]) best matches the EXAFS determined Co–N/O distance of 2.05 Å for **2**. The calculated average Co–N distances for the corresponding N-bound sulfonamide and O-bound sulfone structures are significantly longer at 2.17 Å and 2.14 Å, respectively.

We then compared the reactivities of **2** and **2-Sc** in hydrogen atom transfer (HAT) reactions from the hydrocarbon substrates xanthene, 9,10-dihydroanthracene (DHA), 1,4-cyclohexadiene (CHD), benzyl alcohol (PhCH_2OH) and 1-benzyl-1,4-dihydronicotinamide (BNAH). In all cases, addition of a substrate led to significantly accelerated decay of the chromophore associated with **2** and **2-Sc**. In the presence of an excess substrate this proceeded with first-order kinetics and the resulting effective rate constants (k_{eff}) were found to be linearly dependent upon substrate concentration, thereby yielding second-order rate constants. Such reaction kinetics are consistent with the direct reaction of **2** and **2-Sc** with a substrate or alternatively a rapid pre-equilibrium yielding an alternative active oxidant. Intermediacy of a more traditional imidometal $[(\text{TMG}_3\text{tren})\text{Co}^{\text{IV}}-(\text{NTs})]^{2+}$ oxidant would, therefore, require rapid reversible N–I bond scission. Given that there is no precedence for this and the high energy calculated for the N-bound isomer, which would be a necessary intermediate in its formation, this seems highly improbable. As a consequence, we postulate that the O-bound sulphonamide isomer is the active oxidant.

Table 1 Substrate reactivity studies for **2** and **2-Sc**

Substrate	$\text{BDE}_{\text{C-H}}$ (kcal mol ⁻¹)	Product (% yield) ^a	k_2 (10 ⁻² M ⁻¹ s ⁻¹) at -40 °C	
			2	2-Sc
BNAH	67.6	—	210.1	190.5
Xanthene	74.0	—	2.06	1.14
CHD	76.0	Benzene (65)	1.32	1.38
DHA				

Product analysis of the reaction mixtures of DHA, CHD and PhCH₂OH reactions revealed the formation of the corresponding dehydrogenated products (Table 1) in 52–65% yields;

Fig. 3 Proposed mechanisms for hydrogen atom abstraction from benzyl alcohol based on the dependence of the k_{obs} values of complexes 2 (A) and 2-Sc (B) at -40°C on the concentrations of benzyl alcohol. B inset: expansion of the highlighted region for low concentrations of PhCH₂OH. r.d.s = rate determining step; HAT = hydrogen atom transfer.

Fig. 4 Proposed mechanisms for the hydrogen atom transfer reactions from different substituted phenols based on the dependence of the k_{obs} values of complex 2 on the O–H bond dissociation energies (A), as well as, the pK_a (B) of the phenols. PCET = proton coupled electron transfer; PT = proton transfer; ET = electron transfer; r.d.s = rate determining step.

p-toluenesulfonamide (ArSO₂NH₂; see Fig. 3 and 4) is also detected as a reaction product (80–85% yield) in each case. Control reactions of the substrate with ^sPhINTs alone or with ^sPhINTs + Sc³⁺ did not lead to any oxidation products. Thus, ^sPhINTs is activated upon binding to the {(TMG₃tren)Co^{II}} core. Interestingly, the second order rate constants (k_2) determined at -40°C are comparable both in the absence and presence of Sc³⁺ ions (Table 1). This is in contrast to the previous report of the enhancement of the oxidizing capabilities of the corresponding metal-oxo intermediates^{6,8} in the presence of various Lewis-acids. Furthermore, the k_2 values form a linear correlation (Fig. S10†) with the C–H bond dissociation energies (BDE_{C–H})⁹ of the substrates, which indicates that C–H bond homolysis is the rate determining step (r.d.s) in these reactions.

In order to obtain additional mechanistic insights, deuterium kinetic isotope effects (KIE) on the second-order rate constant $k_2(\text{C–H})/k_2(\text{C–D})$ were measured for reactions of xanthene and DHA with 2. Values of 1.87 and 1.66 were determined at -40°C for xanthene and DHA (Fig. S11A and B†), respectively, indicating that proton transfer is involved in the rate determining step. These KIE values are significantly smaller than those typically seen for high-valent metal-oxo and metal-imido mediated HAT reactions (3–25).^{1,2} This is again consistent with the [(TMG₃tren)Co^{II}–(^sPhINTs)]²⁺ core in 2 not evolving to a reactive high-valent [(TMG₃tren)Co^{IV}–(NTs)]²⁺ species prior to the reaction, and supports the suggestion that it is able to act directly as the reactive species in these oxygenation reactions.

Although the presence of Sc³⁺ did not significantly perturb the rate of C–H bond homolysis mediated by the [(TMG₃tren)Co^{II}–(^sPhINTs)]²⁺ core, it does affect a change in the mechanism in the reaction with PhCH₂OH. As expected, the addition of large excess of PhCH₂OH (30–1000 equivalents) to pre-formed solutions of 2 at -40°C caused pseudo-first order decay (Fig. S12†) of the absorption bands associated with this complex at 420 and 820 nm. Furthermore, the rate of decay was found to increase linearly with increasing PhCH₂OH concentration (Fig. 3A), thereby affording a second order rate constant (k_2) of $0.0020\text{ M}^{-1}\text{ s}^{-1}$. The pseudo-first order rate constants (k_{obs}) for the reaction of 2-Sc with 30–150 equivalents of PhCH₂OH were also observed to follow a linear correlation, and a second order rate constant (k_2) of $0.0037\text{ M}^{-1}\text{ s}^{-1}$ at $-40^\circ\$

This notion is further reinforced by the absence of saturation kinetics for the other substrates, which do not possess a ligating atom, and **2**, which lacks a Lewis acidic binding site.

Mechanistic studies for the reaction of **2** and **2-Sc** with *para*-substituted 2,6-di-*tert*-butylphenols [X-DTBP; X = -OMe, -Me, -^{*t*}Bu, -H, -CN, -CHO, -COOH, -MeC(O)] reveal that the second-order rate constants depend markedly on the electron-donating/-withdrawing properties of the *para*-substituents (Table 1). For all the substituted phenols studied, second order kinetic behavior (Fig. S13†) and identical reaction products, namely ArSO₂NH₂ and two equivalents of the corresponding phenoxyl radical, were observed. However, when the rates obtained for both **2** and **2-Sc** are plotted as a function of σ of the *para*-substituents a linear correlation with a negative Hammett slope (Fig. S14†), as previously reported for the reaction of metal-oxo^{11a} and -superoxo^{11b} intermediates with phenol substrates, is obtained only for the electron-donating substituents (X = -OMe, -^{*t*}Bu, -Me, and -H). The k_2 values for the electron withdrawing substituents [X = -CN, -CHO, -COOH, -MeC(O), -Br] appear significantly above the trend line, thereby hinting at a change in the mechanism for these substrates.

In response, we also plotted the rate constants against the O–H bond dissociation energy (BDE).⁹ Once again, a linear correlation with a negative slope comparable to that obtained for the metal-oxo and -dioxygen intermediates was observed for the phenols with electron-donating substituents, but the data for the phenols with electron-withdrawing groups appeared outside the correlation (Fig. 4A and S15A†). Plotting $\log k_2$ versus $\text{p}K_a$ ¹² (Fig. 4B and S15B†) revealed that for X-DTBP with X = -CHO, -C(O)Me, -CN, -Br, and -H, the rate ($\log k_2$) decreased linearly with decreasing acidity (increasing $\text{p}K_a$), whereas the rates for the electron donating substituents -MeO, -Me, and -^{*t*}Bu scatter irregularly. From the above studies we can conclude that **2** and **2-Sc** oxidize acidic phenols (X-DTBP; X = -CN, -CHO, -COOH, -C(O)Me) *via* a stepwise proton transfer and electron transfer mechanism, with the proton transfer (PT) being effectively rate determining. This is likely to involve an initial proton transfer to solvent (acetone) to give a phenolate anion, which may bind to the Co(II) center and is much easier to oxidize than the phenol itself. The resulting rate acceleration, therefore, parallels the extent of ionization (acidity) of the phenol. In contrast, less acidic phenols like MeO-DTBP, Me-DTBP, and ^{*t*}Bu-DTBP, proceed *via* a concerted proton-coupled electron transfer (PCET) mechanism. Interestingly, data for 2,6-di-*tert*-butylphenol (H-DTBP) falls in all the plots of the second-order rate constant ($\log k_2$) versus the thermochemical parameters BDE_{O–H} and $\text{p}K_a$ (Fig. 4A, B and S15A, B†), thereby locating H-DTBP on the mechanistic borderline between the concerted PCET and stepwise PT-ET reaction pathways.

The reaction of excess triphenylphosphine (30–60 equivalents) with preformed **2** and **2-Sc** at -40 °C leads to the quantitative formation of triphenylphosphonium tosyl-aza-yliide (Ph₃P=NTs) and regeneration of the starting Co^{II} complex **1**. Interestingly, the second order rate constants (k_2)

determined for the reactions of **2** and **2-Sc** with PPh₃ are 0.531 and 0.0321 M⁻¹ s⁻¹, respectively, demonstrating that the group-transfer reactivity of **2** is decelerated by factors of ~15 upon binding of Sc³⁺ ions (Table 1; Fig. S16 and S17†).

Conclusions

In conclusion, we have provided spectroscopic evidence supporting formation of a metal-iminoiodane complex **2** and its scandium adduct **2-Sc**. A novel binding mode of ^sPhINTs *via* the sulfonamide O-atom is predicted in **2** based on DFT calculations. Both **2** and **2-Sc** possess cobalt in a +2 oxidation state. This is in sharp contrast to the analogous oxo chemistry,⁶ where the presence of scandium led to the stabilization of an unusual {Co^{IV}–O–Sc³⁺} core. The formation of the isoelectronic {Co^{IV}–N(Ts)–Sc³⁺} core in **2-Sc**, which would require a short Co–N(Ts) distance, is presumably prevented by the additional steric demands of the tosyl group, which is absent in the oxo chemistry. The reaction of **2** and **2-Sc** with 4-substituted 2,6-di-*tert*-butylphenols is shown to proceed *via* a stepwise PT-ET mechanism for electron withdrawing substituents. Although PT-ET mechanisms have previously been invoked for the oxidation of phenols by organic radicals,¹³ this is the first experimental evidence for a metal complex mediated variant. Additionally, the presence of Sc³⁺ in **2-Sc** is shown to promote the formation of a precursor complex during the oxidation of benzyl alcohol, thereby demonstrating the cooperativity of two metal centers in promoting substrate oxidation reactions. Taken together, the present study expands our understanding of metal-mediated oxidation reactions using iminoiodanes, with metal-im
