## Mayenite-based electride $C12A7e^-$ : an innovative synthetic method *via* plasma arc melting<sup>†‡</sup>

Sebastian Weber,<sup>§a</sup> Sebastian Schäfer,<sup>a</sup> Mattia Saccoccio,<sup>a</sup> Karsten Seidel,<sup>¶b</sup> Holger Kohlmann,<sup>¶c</sup> Roger Gläser<sup>¶d</sup> and Stephan A. Schunk<sup>¶ab</sup>

Mayenite-based electrides have been reported as promising support materials for applications in heterogeneous catalysis. However, the current synthetic access to mayenite materials is limited by a method portfolio of complex procedures far from industrial applicability and thus hinders research and application in a broader context. We report the first plasma-based synthesis of the mayenite-based electride  $[Ca_{24}Al_{28}O_{64}]^{4+}:(4e^-)$  obtained by plasma treatment of oxygen-mayenite solid-reductant precursor mixtures. Aluminum and graphite can be successfully used as solid reductant: while aluminum leads to enhanced secondary phase formation of krotite during the treatment, the use of graphite as solid reductant, leads to phase-pure samples. We further critically discuss challenges and limitations in applying literature reported methods to quantitatively determine the electron concentration of the electrides. For this purpose, EPR-, DRUV/vis-spectroscopy, Rietveld refinement of PXRD and DSC-TG analysis under oxidizing atmosphere were applied and critically revised. We show the possibilities using the facile plasma-based synthesis as a scalable method to obtain semiconducting and close to metallic conducting electrides.

## Introduction

The synthesis of the first crystalline electride  $Cs^+(18\text{-crown-6})_2e^-$  was reported in 1983 by Ellaboudy *et al.* and the structure of this compound could be resolved three years later by Dawes *et al.*<sup>1,2</sup> Based on these studies electrides can be defined as ionic compounds in which electrons act as anions, contained in cavities, while the electron can be delocalized within the cavity.<sup>3</sup> The main challenges regarding applications of the majority of inorganic electrides is their limited thermal stability as these materials are usually reported only to be stable to temperatures up to 240 K.<sup>3</sup> However, the group of Hosono *et al.* pioneered oxide based electride materials in the discovery of the first room temperature stable electride  $[Ca_{24}Al_{28}O_{64}]^{4+}:(4e^-)$

( $C12A7e^-$ ) based on the mayenite structure in 2002 and 2003 with a reported stability up to 673 K under atmospheric conditions.<sup>4–6</sup> The base-compound mayenite is a calcium aluminum oxide with a structure of interconnected cavities.<sup>7,8</sup> The unit cell of this structure consists of a positively charged  $[Ca_{24}Al_{28}O_{64}]^{4+}$  framework forming 12 cages and charge compensating anions inside the cages, which are two  $O^{2-}$  anions in case of the common oxygen mayenite  $[Ca_{24}Al_{28}O_{64}]^{4+}:(2O^{2-})$  ( $C12A7$ ).<sup>9–12</sup> The structure is known as a host-material to a variety of anionic species as reviewed by Salasin *et al.*<sup>13</sup> Anionic guest species that are of special interest for this work are  $OH^-$ ,<sup>14</sup>  $O_2^-$ ,<sup>8,15</sup>  $O^-$ ,<sup>15,16</sup>  $O_2^{2-}$ ,<sup>8</sup>  $H^-$ ,<sup>4,17</sup>  $N^{3-}$ ,<sup>18</sup>  $NH_2^-$ ,<sup>18,19</sup>  $NH^{2-}$  (ref. 20) and  $C_2^{2-}$ .<sup>6,21–24</sup>

According to the respective electronic properties the mayenite electride system  $[Ca_{24}Al_{28}O_{64}]^{4+}:(2 \times \delta)e^-:(2 - \delta)O^{2-}$  can be roughly distinguished into insulating ( $\delta = 0$ ,  $N_e = 0 \text{ cm}^{-3}$ ), semiconducting ( $\delta < 1$ ,  $N_e < 1 \times 10^{21} \text{ cm}^{-3}$ ) and metallic conducting ( $\delta > 1$ ,  $N_e > 1 \times 10^{21} \text{ cm}^{-3}$ ) materials depending on the respective electron concentration ( $N_e$ ). The maximum electron concentration of  $N_e = 2.3 \times 10^{21} \text{ cm}^{-3}$  can be obtained if all oxygen anions are replaced by electrons.<sup>5,6,13,25</sup> One indicator for the different electron densities/concentrations is the color of the material. The insulating oxygen-containing mayenite  $C12A7$  is a colorless solid with a band gap of about  $\sim 7 \text{ eV}$ , semiconducting mayenite based electrides  $C12A7e^-$  have a green color with a band gap of about 0.4 eV while the metallic conducting  $C12A7e^-$  have a very dark or black appearance with a work function of about 2.4 eV.<sup>5,6,13,25,26</sup> An interesting

application of  $\text{C12A7e}^-$  was reported as catalyst support material for ammonia synthesis using a  $\text{Ru/C12A7e}^-$  catalyst by the group of Hosono.<sup>27</sup> Electron donation from the support to the active Ru metal and reversible hydride formation inside the  $\text{C12A7e}^-$  cages were highlighted as important promoting effects for the enhanced activity as support material for Ru-based ammonia synthesis catalysts.<sup>27–30</sup> The group also reported that the activity of the catalyst is dependent on the electron concentration of the  $\text{C12A7e}^-$  support, with metallic conducting  $\text{C12A7e}^-$  support materials leading to remarkably higher activity.<sup>29,30</sup> The  $\text{Ru/C12A7e}^-$  catalyst showed a TOF of up to  $0.98 \text{ s}^{-1}$ , which is more than one order of magnitude higher than conventional promoted  $\text{Ru-Ba}/(\text{activated carbon})$  or  $\text{Ru-Cs/MgO}$  ammonia synthesis catalysts.<sup>27</sup> A more detailed overview about further catalytic and other applications can be found in a recent review by Khan *et al.*<sup>25</sup>

The industrial scale application of  $\text{C12A7e}^-$  is hampered, amongst other factors, by challenges associated to the synthesis methods reported up to now. In general, the portfolio of methods can be divided in two conceptual groups: removal of oxygen *via* reduction through compounds interacting over the gas-phase or reduction through compounds interacting *via* solid-state reaction. The formation of  $\text{C12A7e}^-$  was first described by Hayashi *et al.* *via* a reduction of  $\text{C12A7}$  with hydrogen at 1573 K for 2 h with a subsequent UV light illumination, however only semiconducting electrides can be obtained *via* this route.<sup>4</sup> Another reported reduction method *via* gas/solid reaction is the use of a  $\text{CO}/\text{CO}_2$  atmosphere inside of graphite crucibles by heating of  $\text{C12A7}$  to 1473 or 1873 K to obtain semiconducting  $\text{C12A7e}^-$ .<sup>21,31</sup> Applying gas/solid reduction methods appears to be difficult:  $\text{C12A7e}^-$  with high electron concentrations and thus metallic conducting properties is rarely reported *via* this approach.<sup>13,25</sup> Successful synthesis with higher electron concentrations in the mayenite electrides mainly relies on procedures based on solid-state reduction;<sup>12,13,25</sup> solid-state reduction in this case refers to the use of materials which act as reductants in solid or molten form. We only intend to provide a short overview on some solid-state procedures, for more complete and detailed overviews on reported synthesis procedures of  $\text{C12A7e}^-$  the reader is referred to reviews by Kim *et al.*, Salasin *et al.* or Khan *et al.*<sup>12,13,25</sup> The first successful synthesis of metallic conducting  $\text{C12A7e}^-$  was reported by the group of Hosono. In this method, the oxygen in the  $\text{C12A7}$  single crystals was removed with calcium at 973 K for 240 h in evacuated silica tubes ( $10^{-4} \text{ Pa}$ ) leading to formation of  $\text{C12A7e}^-$  and  $\text{CaO}$ , while the latter one was removed by polishing.<sup>5</sup> Another reduction method using metal-based reductants introduced by the same group was the use of titanium powder as reductant at 1373 K for 24 h in evacuated silica tubes ( $10^{-1} \text{ Pa}$ ).<sup>32</sup> The difference between the use of titanium compared to calcium is the formation of  $\text{TiO}_2$  as by-product instead of  $\text{CaO}$ . Both procedures are reported to allow to achieve a complete exchange of the cage oxygen by electrons.<sup>12</sup> Furthermore, vanadium is reported for heating  $\text{C12A7}$  in metallic vanadium foil at 1273 K for 24 h in vacuum ( $10^{-3} \text{ Pa}$ ) by Palacios *et al.*<sup>10</sup> The main drawbacks of the

pathways using metals as reductants are synthesis under vacuum conditions, high temperatures, long reaction times, potential secondary phase formation and limited scalability of the procedures. Khan *et al.* recently reported strategies which used aluminum calcium precursor gels *via* the sol-gel method out of nitrates. Those were heated after further processing steps in an aluminum furnace for 1 h at temperatures up to 1823 K to obtain metallic conducting  $\text{C12A7e}^-$ .<sup>33,34</sup> Further solid-state reduction synthesis procedures are reported for using different carbon precursors as reductants at about 1673 K by Volodin *et al.* and Jiang *et al.*, however those methods only lead to semiconducting electrides with intermediate electron concentration.<sup>23,24</sup> Recent studies with sparkling plasma sintering strategies are reported by Li *et al.* which led to metallic conducting electrides enabling much shorter synthesis durations.<sup>35–37</sup> Though this process leads to dense ceramics well suited for electrical applications, the scale-up potential to obtain large amounts of powder material necessary for an application as a catalyst support seems challenging. Similar to studies by Khan *et al.*, Salasin *et al.* and Li *et al.* showed the possibility to obtain electrides by synthesis from different Ca and Al precursor compounds and not the preformation of  $\text{C12A7}$ .<sup>33–38</sup> A big step towards the batch synthesis of larger amounts of  $\text{C12A7e}^-$ , in respect of an application as a catalyst support, was accomplished by Jiang *et al.* by aluminothermic synthesis using a mixture of  $\text{CaO}$ ,  $\text{Al}_2\text{O}_3$  and Al and heating under Ar at 1373 K for 8 h.<sup>39</sup>

Besides challenges in the synthesis of the  $\text{C12A7e}^-$  material, its characterization and especially the determination of its electron concentration are not trivial. The exact determination of the crystallography of electride solids based on the mayenite structure type is difficult due to the variation of anion species in the cages. The structure can show strong distortions as described by Palacios *et al.*, Boysen *et al.* or Sakakura *et al.*<sup>10,11,40,41</sup> In general, they describe the structure as a superposition of three cage types: free cages, occupied cages and cages adjacent to occupied cages. A substitution of oxygen by electrons in the cages thus leads to a larger number of occupied cages – which in turn leads to structural distortions depending on the electron concentration as reviewed by Salasin *et al.*<sup>13</sup> As the semiconducting stage of  $\text{C12A7e}^-$  is characterized by a color change from colorless to green, which is attributed to formation of F-centers comparable to halides, electron paramagnetic resonance (EPR) spectroscopy and diffuse reflectance UV/vis (DRUV/vis) spectroscopy are reported to analyze the electron concentration.<sup>5,42–45</sup> EPR spectroscopy can show the presence of F-centers regardless of the electron concentration, while a quantitative determination was only possible for  $N_e < 5 \times 10^{19} \text{ cm}^{-3}$ .<sup>5</sup> Another method reported for determination of the electron concentration was thermogravimetric (TG) analysis under oxidizing atmosphere.<sup>42,45,46</sup> Furthermore, structural characterization by Rietveld refinement of XRD and NPD data was reported to allow determination of the electron concentration *via* refinement of the occupancy of the anion position inside the cages.<sup>5,42</sup> Conductivity measurements are also reported as adequate to enabled to determine the electron

concentration. For single crystalline  $\text{C}12\text{A}7\text{e}^-$  the group of Hosono *et al.* found an electron concentration of  $N_e = 2.3 \times 10^{21} \text{ cm}^{-3}$  with a conductivity of  $1500 \text{ S cm}^{-1}$  while for polycrystalline  $\text{C}12\text{A}7\text{e}^-$  Khan *et al.* recently reported a highest achieved conductivity of  $28 \text{ S cm}^{-1}$  with an electron concentration of  $N_e = 1.9 \times 10^{21} \text{ cm}^{-3}$ .<sup>4,5,26,33,34,47</sup> However, Khan *et al.* only used conductivity measurement and no complementary method to determine the concentration. Only for some special cases Raman spectroscopy, SQUID measurements are reported as ways to investigate the electron concentration.<sup>5,43</sup> Iodometric titration is also used frequently, however the role of metal impurities such as Al or Ca might influence the results as reported by Jiang *et al.*<sup>39,45</sup>

Existing strategies for the synthesis of solid electrides reported in the literature mainly refer to bulk/batch synthesis and are thus limited in their scalability. In this work, we report the first plasma-based synthesis of mayenite electrides, which is a convenient, fast and scalable production method for this material.<sup>48–50</sup> The drawbacks of conventionally reported synthesis methods can thus be circumvented, and the procedure is in general applicable and interesting for an industrial scale production of advanced materials like mayenite electrides.

First, we discuss the different solid-state precursor materials and conditions applied in plasma which were tested and their influence on the properties of the obtained material by rigorous and thorough characterization. Afterwards we discuss challenges, obstacles and limitations observed in quantitatively analyzing the electron concentration of the obtained electrides, which were characterized by DRUV/vis spectroscopy, EPR spectroscopy, DSC-TG analysis and Rietveld refinement of PXRD. The results obtained in applying the different methods are compared and limits of these characterization methods in their application as routines for the determination of the electron concentration in these materials are critically reviewed and discussed.

## Experimental

### Synthesis

Synthesis of mayenite ( $\text{C}12\text{A}7$ ) was carried out by wet mixing of Ca- and Al-oxide precursors followed by calcination. For the synthesis of 100 g  $\text{C}12\text{A}7$  the following procedure was used: 43.65 g calcium oxide (reagent grade, Sigma Aldrich), 56.91 g Disperal P2 (Sasol) and 150 mL deionized water were mixed in a ball mill at 600 rpm for four times with alternating direction of rotation for each 10 min with a break of 5 min for cooling between each milling step. Afterwards, the paste was heated in a muffle furnace to 1373 K with a ramp of  $5 \text{ K min}^{-1}$  and a holding time of 8 h under a constant flow of clean dry air (CDA). After this calcination, the obtained solid was crushed and grinded with a mortar and pestle and analyzed by powder X-ray diffraction (PXRD). Batches with excessive krotite (CA) and tricalcium aluminate (C3A) secondary phases were calcined a second time to decrease the amount of secondary phase.

For synthesis of mayenite-based electrides ( $\text{C}12\text{A}7\text{e}^-$ ) an arc furnace “Compact Arc Melter MAM-1” by Edmund Bühler

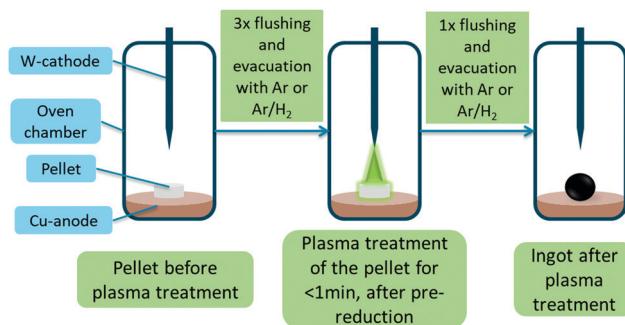

Fig. 1 Illustrated treatment steps for plasma treatment of pellets inside the arc furnace.

GmbH was used. Experiments were carried out either under Ar or 95% Ar/5%  $\text{H}_2$  (Arcal 15, Air Liquide) atmosphere. The furnace consists of a static water-cooled copper crucible plate and a water-cooled, manually operated, movable tungsten electrode. The oven chamber is connected to a built-in roughing vacuum pump and gas connection. The plasma intensity can be controlled *via* a current regulator. A calibration curve of the estimated plasma power depending on the plasma intensity setting from the current regulator is shown in the ESI,‡ Fig. S1. The general plasma treatment procedure is illustrated in Fig. 1. Prior to all experiments, the chamber was each three times evacuated and flushed with the desired gas. In general, a pressure of 0.7 bar of the gas inside the chamber was used during plasma treatment. Before starting the actual treatment of the sample, the plasma was once ignited without approaching the sample and the chamber was evacuated and flushed once more. This process is seen as kind of “pre-reduction” step to evaporate adsorbed  $\text{H}_2\text{O}$  either from the sample or furnace parts. After treatment, the chamber is generally evacuated and flushed with the process gas mixture, before the chamber is filled with air to be opened.

Most samples studied were treated as pellets. For this purpose, synthesized  $\text{C}12\text{A}7$  was thoroughly mixed with different solid reductants, which are similar applied to getter materials, as listed in Table 1. The obtained mixtures were pressed with 10 t using a motorized pellet press resulting in pellets with a diameter of 13 mm and mass of about 0.5 g per pellet. Aluminum powder 99.5% metals basis by Alfa Aesar and graphite powder general purpose grade by Fischer Chemical were used as solid reductants. The pellets listed in Table 1 were treated until a homogeneous melting could be observed, which usually takes less than 1 min. At times, to obtain a homogeneous melt, the ingots needed to be flipped and treated on the bottom-side as well, as indicated in Table 1.

Powders of  $\text{C}12\text{A}7$  and mixtures with solid reductants without pressing were plasma treated by two methods (I) wrapping in graphite foil, (II) using a carbon crucible. For (I) samples were wrapped in 0.2 mm thick SIGRAFLEX® carbon foil pieces with a size of 2.5 cm × 4 cm. For (II) powders were filled in a custom-made graphite crucible with an inner diameter of 17 mm and inner height of 8 mm closed with a graphite lid allowing treatment of 0.5 g powder. Plasma intensity and

**Table 1** List of samples obtained by plasma treatment of pellets. Plasma intensity  $I_{\text{Plasma}}$  according controller of the arc furnace, cycles as 'times top-side'x, 'times bottom-side'x treatment

Sample ID	Solid reductant	Atmosphere	$I_{\text{Plasma}}$	Cycles
(a) C12A7	None	Ar	5	3x1x
(b) C12A7e <sup>-</sup>	None	95% Ar/5% H <sub>2</sub>	5	6x0x
(c) C12A7e <sup>-</sup> (20 wt% Al)	20 wt% Al	95% Ar/5% H <sub>2</sub>	5	1x1x
(d) C12A7e <sup>-</sup> (3 wt% C)	3 wt% graphite	95% Ar/5% H <sub>2</sub>	5	3x0x
(e) C12A7e <sup>-</sup> (3 wt% C)	3 wt% graphite	95% Ar/5% H <sub>2</sub>	5	2x1x
(f) C12A7e <sup>-</sup> (5 wt% C)	5 wt% graphite	95% Ar/5% H <sub>2</sub>	5	1x1x
(g) C12A7e <sup>-</sup> (3 wt% C)	3 wt% graphite	95% Ar/5% H <sub>2</sub>	5	1x1x
(h) C12A7e <sup>-</sup> (3 wt% C)	3 wt% graphite	95% Ar/5% H <sub>2</sub>	5	1x0x

treatment duration for achieving homogeneous products with both methods were estimated in initial tests, since visible control of the materials during plasma treatment is not possible. For both (I-II) the established "pre-reduction" step was done before samples were once treated with plasma intensity of 3 for 60 to 90 s followed by once flushing and evacuating the oven chamber with the process gas mixture before removing the sample.

Alternative to graphite as a carbon-based solid reductant, glucose was tested as carbon precursor, which is known as a sustainable carbon source from literature.<sup>51</sup> 5 g C12A7 were impregnated with 0.626 g (5 wt% C equivalent) or 1.389 g (10 wt% C equivalent) glucose in 75 mL H<sub>2</sub>O. During impregnation C12A7 was suspended in the solution in an ultrasonic bath. The suspensions were dried at 353 K for 1 h in a compartment dryer before the powder was carbonized under a nitrogen stream at 873 K for 1 h with a heating rate of 5 K min<sup>-1</sup>. C12A7 glucose-based solid reductants were treated as pellets. Besides Al, Ca was used as metallic solid reductant as described in the literature before.<sup>5</sup> Ca or CaH<sub>2</sub> were mixed with C12A7 inside an Ar filled glovebox before they were plasma treated in the graphite crucible. The mixture was directly filled into the crucible in the glove box while a short exposure to atmospheric conditions during the transfer of the crucible to the plasma oven was inevitable. Samples for alternative solid reductants experiments are summarized in Table 2.

Ingots obtained after plasma treatment for samples listed in Table 1 were directly transferred into an Ar filled glovebox where they were ground in an agate mortar and stored under inert conditions. Samples from Table 2 were handled under atmospheric conditions, except samples with Ca as solid reductant that were directly transferred into the glovebox.

## Characterization

EPR spectra were recorded using a MS 100 X-Band-EPR-Spectrometer by Magnettech. The spectra were recorded at

**Table 2** List of samples obtained by using different carbon-based solid reductants and Ca. Plasma intensity  $I_{\text{Plasma}}$  was 3 for all treatments in graphite crucibles and 5 for pellets

Sample ID	Solid reductant	Atmosphere	Container	Cycles
(i)	5 wt% glucose	95% Ar/5% H <sub>2</sub>	Pellet	3x1x
(j)	10 wt% glucose	95% Ar/5% H <sub>2</sub>	Pellet	6x0x
(k)	5 wt% Ca	Ar	Crucible	1x1x
(l)	10 wt% Ca	Ar	Crucible	1x1x
(n)	10 wt% CaH <sub>2</sub>	Ar	Crucible	1x0x

room temperature with  $B_0 = 340.0$  mT,  $B_0, \text{sweep} = 49.9$  mT, sweep time  $t_{\text{sweep}} = 500$  s, 4096 steps, modulation amplitude MA = 0.1 mT, a microwave attenuation MWA = 10 dB and a microwave power MWP = 10 mW. The gain (GA) was fit for each sample. For the measurements the samples were filled into 50  $\mu$ L Duran<sup>®</sup> glass micro pipettes by Hirschmann Laborgeräte GmbH, which were closed with clay. In order to compare the experiments, the measured first derivative of the spectra was integrated to obtain the absorption spectra. The absorption peak was then integrated with a linear background correction. To compare the obtained integrals, these were normalized using eqn (1), where  $I_N$  is the normalized integral in arbitrary units (a.u.),  $I_{\text{EPR}}$  the integral of the absorption peak in a.u., GA the gain, MA the modulation amplitude, MWP the microwave power and  $m_{\text{sample}}$  the sample mass. Additional ESR measurements were carried out using an X-band MiniScope MS5000 CW spectrometer (Freiberg Instruments) with a field homogeneity of  $\pm 5$   $\mu$ T within the sample region, 0.2 mT field modulation and 100 kHz modulation frequency. The samples were irradiated at 35 mW RF power and 9.47 GHz frequency acquiring 1 scan for 540 s at RT. The magnetic field  $B_0$  range was chosen 300–380 mT. The  $g$ -factors for the selected samples were determined using EasySpin 5.2.20.<sup>52</sup>

$$I_N = \frac{I_{\text{EPR}}}{(GA \cdot MA \cdot m_{\text{sample}} \cdot \sqrt{MWP})} \quad (1)$$

Powder X-ray diffraction (PXRD) analysis was done using a Bruker D8 ADVANCE diffractometer with Bragg–Brentano geometry, a LynxEye XE 1D-detector, a Cu-X-ray-tube with Cu-K<sub>α1</sub>  $\lambda = 154.06$  pm and Cu-K<sub>α2</sub>  $\lambda = 154.44$  pm and a ratio of Cu-K<sub>α1</sub>:Cu-K<sub>α2</sub> = 2. The samples were prepared by thoroughly grinding the desired material in an agate mortar. The samples were measured on flat sample holders consisting of poly(methyl methacrylate). For standard qualitative measurements the diffraction pattern was measured in a range of  $2\theta = 10^\circ$ – $90^\circ$  with a step size of 0.0205° and measuring time of 0.2 s step<sup>-1</sup>. For Rietveld refinements the measuring parameters were  $2\theta = 10^\circ$ – $140^\circ$  with a step size of 0.005° and measuring time of 0.2 s step<sup>-1</sup>. PXRD data was analyzed using Match! – Version2 software by Crystal Impact GbR for quick qualitative phase analysis and FullProf<sup>53</sup> software by J. Rodriguez-Carvajal for Rietveld refinements. CIF files for phase analysis and as starting models for Rietveld refinement were obtained from Crystallography Open Database (COD)<sup>54</sup> or Inorganic Crystal Structure Database (ICSD).<sup>55</sup> The composition of the samples was

either determined by semi quantitative phase analysis using Match! – Version2 or as a result of Rietveld refinement using FullProf.

For STA measurements a STA 449 F3 Jupiter<sup>®</sup> by NETZSCH was used, with a combination of differential scanning calorimetry (DSC) and thermogravimetric analysis (TG). The apparatus can be run using nitrogen or synthetic air up to 1573 K. The general heating rate was 10 K min<sup>-1</sup>. The samples were measured in corundum crucibles and typically about 10 mg sample were used. According to the literature<sup>42,46</sup> oxygen oxidizes the mayenite-electride which leads to an uptake of oxygen and thus a mass gain. The theoretical mass gain from the electride with the maximum electron number to the stoichiometric oxygen-mayenite is 1.17 wt%. Due to this small value the sensitivity and error of the method were determined by multiple STA measurements under nitrogen and synthetic air for four different mayenite and mayenite-electride samples.

Diffuse reflectance UV-vis (DRUVVis) experiments were carried out using a PerkinElmer Lambda 950 spectrometer with an included 150 mm Ulbricht-sphere by Labsphere. The reference for the reflection measurement was a Spectralon<sup>®</sup> white standard by Labsphere. The spectra were recorded in a wavelength range from 200 to 2500 nm with an acquisition speed of 250 nm min<sup>-1</sup>, integration time of 0.2 s and data interval of 1 nm at room temperature. The reflection spectra were processed according to the literature<sup>5,42–44</sup> with the Kubelka–Munk transformation using the following equation:

$$F(R) = \frac{(1 - R)^2}{2R} \quad (2)$$

where  $R$  is reflectance and  $F(R)$  the Kubelka–Munk function. The obtained Kubelka–Munk function is used for an estimation of the electron concentration  $N_e$ . For this purpose, relation (3) reported by Matsuishi *et al.* is used:<sup>44</sup>

$$N_e = \left[ \frac{-(E_{sp} - E_{sp}^0)}{0.119} \right]^{0.782} \quad (3)$$

where  $N_e$  is the number of electrons in  $10^{21}$  cm<sup>-3</sup>,  $E_{sp}$  is the position of the maximum of the absorption peak around 2.8 eV in eV, and  $E_{sp}^0 = 2.83$  eV for a  $N_e = 1 \times 10^{18}$  cm<sup>-3</sup>. It must be noted, however, that no source or derivation for this relation is provided by Matsuishi *et al.* and the results should be taken carefully, as it will be discussed in the discussion.<sup>44</sup> Spectra were analyzed using OriginPro software. Determination of the maximum position was carried out as follows: (1) smoothing the Kubelka–Munk transformed spectra using a FFT filter (2) calculating the first derivative (3) determining the maximum position from the zero value of the first derivative in the range around  $E_{sp} = 2.8$  eV. The energy resolution of the measurement was 0.01 eV, the error for the determination of the maximum position is estimated to be  $\pm 0.02$  eV, which results in an error of the number of electrons.

TEM measurements were carried out with a FEI Osiris TEM. The acceleration voltage was 200 kV. The samples were prepared by dispersing the sample with EtOH between two glass

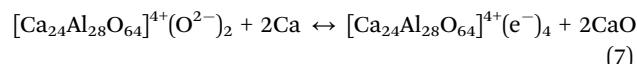

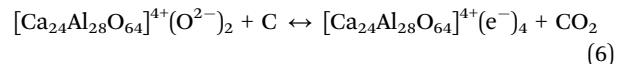

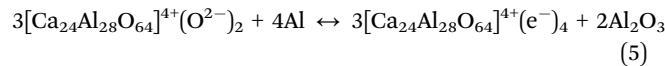

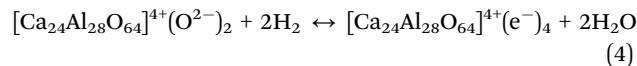

object slides. In this dispersion a graphite-covered Cu net was dipped, which is used as sample holder for the measurement.

## Results and discussion

In the following discussion we first focus on the successful synthesis of C12A7e<sup>-</sup> by plasma treatment while discussing the influence of different solid reductants and treatment variations of powders. In the first subsection, we analyze in detail the properties of selected samples mainly focusing on their phase purity and the different synthetic procedures while discussing the electron concentration only qualitatively. Finally, in the second subsection, we critically discuss the suitability of some of the methods reported in the literature for the determination of a relevant property as the electron concentration for samples of our pellet-based synthesis approach. At the current state, we expect that the treatment of the precursors with the plasma is mainly a fast thermal process, as the precursors in case of the pellet route were treated until a homogeneous melting was observed and the foil or crucibles in case of the powder route were heated by the plasma.

### Plasma synthesized electrides

**Influence of different solid reductants and reaction atmosphere.** In this work, we synthesized mayenite-based electrides (C12A7e<sup>-</sup>) for the first time successfully by plasma synthesis in an arc furnace as a new synthetic method. For this purpose, oxygen-rich mayenite (C12A7) was used as precursor mixed with different types of solid reductants (Al or C-based) as summarized in Table 1. Plasma synthesis was carried out using two different atmospheres, Ar and Ar with 5% H<sub>2</sub>: the latter one is expected to create a reducing atmosphere potentially able to reduce the precursor to form an electride. In general, a requirement for the synthesis of C12A7e<sup>-</sup> is the removal of the inter-cage oxygen atom of the C12A7 precursor while retaining an electron within the cage. For this purpose gaseous reductants such as H<sub>2</sub> or solid reductants like Al, C or Ca are be possible. These reductants can act similar to a getter material as a scavenger for the inter-cage oxygen *via* the following reactions, assuming a complete exchange of the inter-cage oxygen:

In Fig. 2, treated pellets of the C12A7-precursor mixtures are shown as ingots after treatment, powders after grinding of the ingots and respective EDX maps obtained by TEM studies. A first indication of the presence of a mayenite electride is obtained by changes in the observed color, while

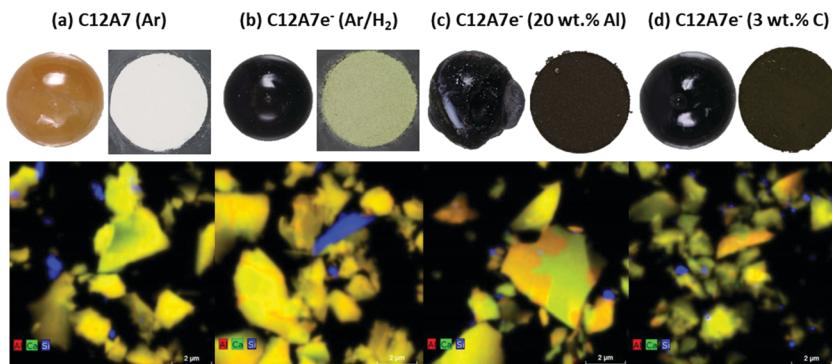

Fig. 2 Top: Pictures of ingots obtained after plasma treatment and powders after grinding of the ingots; bottom: EDX maps of TEM studies of (a) pure C12A7 treated under Ar atmosphere, (b) pure C12A7 treated under 95% Ar/5% H<sub>2</sub> atmosphere, (c) 20 wt%-Al/C12A7 mixture treated under 95% Ar/5% H<sub>2</sub> and (d) 3 wt%-C/C12A7 mixture treated under 95% Ar/5% H<sub>2</sub>. The EDX images show the distribution of Al (red), Ca (green) and the ratio (yellow to orange) of both. Si (blue) is present due to TEM sample preparation. Orange areas are assigned to CA (krotite) secondary phase and yellow areas to C12A7 based on different Ca to Al ratios in the two phases.

detailed analysis of the electron concentration is discussed later. Treatment of pure C12A7-precursor under Ar atmosphere (a) does not lead to a color change after grinding of the treated sample. For treatment of pure C12A7-precursor under reductive plasma atmosphere (b), *i.e.* Ar with 5% H<sub>2</sub>, results in formation of mayenite electrides indicated by the greenish color of the powder which is in line with reports from literature for C12A7e<sup>-</sup> with low electron concentration.<sup>5</sup> Plasma treatment using a reductive atmosphere is found to be useful to yield electrides with low electron concentration; combining plasma treatment under reductive atmosphere with the addition of a solid reductant to the mix is the method of choice for increasing electron concentration, as shown below. In addition to the limited electron concentration, the treatment of pure C12A7 under reducing atmosphere to obtain C12A7e<sup>-</sup> presents other challenges, namely the formation of secondary phases, and the need of multi-steps process, each step consisting in an evacuation, a filling with fresh process gas mixture and the plasma treatment. Based on our empirical observation throughout the hundreds of syntheses performed for this work, we expect that the limiting factor for the reduction is the formation of water during the treatment and the removal thereof and not the consumption of hydrogen. For the C12A7e<sup>-</sup> sample (b) in Fig. 2 6 wt% krotite (CA) and 16 wt% penta calcium tri aluminate

(C5A3) were observed as secondary phases by PXRD analysis combined with Rietveld refinement (see Table 3).

Addition of solid reductants like (c) Al or (d) C in form of graphite shows increases in electron concentration combined with a reduced number of required steps to reach higher electron concentrations visible through apparent color change. The addition of either solid reductants results in dark green/brown to black color of the ingots and the powders after grinding of the ingots as shown in Fig. 2, suggesting a higher electron concentration. Based on these results we can already infer that the plasma treatment of C12A7 mixtures in the presence of solid reductants enables the synthesis C12A7e<sup>-</sup> with high electron concentrations.

A major problem in using Al as solid reductant (c) is the resulting high amount of secondary phase leading to about 55 wt% CA secondary phase with only 45 wt% C12A7e<sup>-</sup> based on Rietveld refinement (the balance for refinement was only made for oxygen containing phases metallic Al visible as small grains attached to the ingots were not considered). The high amount of Al as solid reductant was necessary to obtain homogeneously colored black ingots and a resulting higher electron concentration. Preparation using only 5 or 10 wt% Al resulted in electride materials with a much brighter greenish color. The phase diagram of calcium aluminates can explain

Table 3 Parameters obtained from Rietveld refinement of PXRDs from powders after plasma treatment as shown in Fig. 6. As initial structural model for refinement the structure by Sakakura *et al.* was used.<sup>41</sup> The quality of the PXRD data was not sufficient for reliable refinement of atomic parameters, therefore values of the literature-based model were kept fixed

the strong formation of CA secondary phase with the higher  $\text{Al}_2\text{O}_3$  content in the system formed during the reduction process as described by eqn (5).<sup>13</sup>

The use of carbon in form of powdered graphite as solid reductant (*d*) led to a product with a color in a similar range compared to Al addition. Advantageously, however, the amount of secondary CA phase was determined to be about only 10 wt%. As for an application in catalysis, high content of secondary phases may be critical, or lead to dubious conclusions, we consider this finding important. Secondary phase formation may be especially problematic if it takes place on the surface of the desired  $\text{C}12\text{A}7\text{e}^-$  phase leading to decreased surface area and accessibility of the electride or may be coupled to secondary effects like decreased stability. Any physical separation of the primary and secondary phase appeared so far not possible for the obtained products. EDX mapping by TEM shows clear presence of the secondary CA phase (orange) together with  $\text{C}12\text{A}7$  phase (yellow) in same particles forming common grain boundaries as shown in Fig. 2. The formation of the electride by addition of graphite as solid reductant presumably proceeds *via* eqn (2) with the formation of  $\text{CO}_2$  or not shown in the equation formation of CO.

Based on these results we can conclude that the use of minor amounts (<5 wt%) of graphite addition is the most promising and favored way to obtain phase-pure mayenite electride materials with a high electron concentration by plasma treatment in a reducing atmosphere. Detailed characterization results to quantitatively determine the electron concentration are discussed in the Determination of electron concentration subsection. In general, the use of both solid reductants, aluminum and carbon, is practical, cheap and safe.

**Plasma treatment of powders.** We tested the plasma treatment of powders, without pelletizing them first, to potentially increase electron concentrations and elaborate the scale-up potential of the method to a continuous process. Due to the evacuation procedure and the flushing process a direct treatment of powders in the arc furnace appears not to be possible due to dislocation of the powder in the reaction chamber. Nevertheless, treatment of powders was carried out either by wrapping the desired mixture in graphite foil or by using a custom-made graphite crucible with a graphite lid which could be directly heated by the plasma. The different treated powder samples are summarized in Table 2.

Treating pure  $\text{C}12\text{A}7$  precursors wrapped in graphite foil resulted in dark ingots though powders after grinding only showed a bright greyish color. Therefore, it is not assumed that an mayenite material with electride properties could be successfully synthesized. PXRD analysis shows mainly presence of initial  $\text{C}12\text{A}7$  phase, for some tests  $\text{C}5\text{A}3$  or graphite from the foil attached to the ingots were observed as secondary phases. Ingots with attached graphite foil pieces were a general problem using graphite foil as reaction container and such pieces could in general not be removed manually from samples. Treatment of pure  $\text{C}12\text{A}7$  in the graphite crucible showed no improvement in electron concentration based on visual observation and color inspection of the powders after grinding.

Benefits using the graphite crucible were the avoidance of graphite foil pieces attached to the ingots, reduced secondary phase formation and a more controlled treatment possibility. Treatment of samples in foil often lead to holes burnt in the foil locally or non-heated parts of the precursor showing macroscopically heterogeneous product formation and unreacted precursor material after plasma treatment.

Wrapping the powders in graphite foil allowed testing Ca and  $\text{CaH}_2$  as solid reductants. Stable pellets could indeed not be obtained for mixtures containing Ca or  $\text{CaH}_2$  under the conditions applied for the pellet preparation of the other materials reported, as the pelletizing step required exposing the powder to air, which would cause Ca and  $\text{CaH}_2$  to react. Addition of Ca for the synthesis of  $\text{C}12\text{A}7\text{e}^-$  with heating under vacuum is the most common method reported in the literature for metallic conducting electrides.<sup>12,13,25</sup> Furthermore, carbon containers are thought to enhance electron concentration by acting as a further oxygen scavenger or a solid material acting as precursor for the creation of reductive atmospheres. Carbon crucibles have been reported in the literature for synthesis of  $\text{C}12\text{A}7\text{e}^-$  though no plasma treatment of the crucible was done, they were solely used as containers/furnaces for heating.<sup>22,24</sup> Based on our results we conclude that in our case the foil or crucible is also only acting as a container for the material, while the container is heated *via* the thermal plasma.

Using powder mixtures of  $\text{C}12\text{A}7$  with either C, Ca or  $\text{CaH}_2$  solid reductants as precursors resulted in black ingots for both containers. Resulting powders showed light grey to dark green colors indicating electride formation. Compared with the dark brown to black color visible for pellet treatment of  $\text{C}12\text{A}7$  graphite or aluminum mixtures no increased electron concentration was observed. Electride formation with Ca or  $\text{CaH}_2$  did not show an increased visible electron concentration based on the color compared to treatment of 3 wt%-C  $\text{C}12\text{A}7$  pellets. PXRD for Ca and  $\text{CaH}_2$  prepared  $\text{C}12\text{A}7\text{e}^-$  show formation of 10 to 14 and 35 wt%  $\text{Al}_6\text{Ca}_9\text{O}_{18}$  secondary phase, respectively.

Products mentioned in this section were generally only analyzed with PXRD for phase composition of crystalline phases and electron concentration are only judged based on visual impression by the apparent color of the material. Plasma treatment of powders was found to be possible in both containers while the carbon crucible allowed more reproducible results and a more controlled treatment. However, we found no advantage in terms of the general handling or increased electron concentration and reduced secondary phase amount compared to the primary pellet-based approach, even when highly reactive Ca and  $\text{CaH}_2$  were used as solid reductants.

**Alternative carbon-based solid reductants.** Based on the pellet-based approach, we found graphite to be the optimum solid reductant regarding high electron concentration with tolerable secondary phase formation. Though one problem of graphite is the mixing with  $\text{C}12\text{A}7$  precursor as it is greasy and obtaining a homogenous mixture might be difficult. For this reason, glucose as a soluble carbon source was tested for its potential use as replacement of graphite as solid reductant. The general idea behind the concept is wet impregnation of  $\text{C}12\text{A}7$

with a carbon precursor source by wet impregnation followed by carbonization forming graphitic carbon species acting as the later solid reductant. Production of C12A7 $e^-$  using C12A7 encapsulated in polyvinyl alcohol (PVA) based carbon derived from carbonization is reported in a work of Volodin *et al.*<sup>23</sup> However, Volodin *et al.* reported a maximum electron concentration of  $2.0 \times 10^{19} \text{ cm}^{-3}$  corresponding to a semiconducting C12A7 $e^-$  material. Therefore, no significant improvement of this method compared to the general synthetic procedure could be achieved – except for a higher dispersity of the sample compared to most reported metal solid reductant based high temperature methods, which result in dense ceramics.<sup>13,25</sup> The two different samples with glucose as carbon source and the treatment conditions are summarized in Table 2. Glucose as carbon precursor impregnated on mayenite resulted in grey to green powders after grinding of ingots obtained by plasma treatment. This color change indicates formation of semiconducting C12A7 $e^-$  though reproducibility appeared to be difficult. The same issues regarding use of graphite as solid reductant were observed for secondary phase formation ranging from 3 wt% CA up to 7 wt% CA and in some cases C5A3 amount up to 33 wt%. Differences in electron concentration can be explained by oxygen content of the initial carbon source. It is expected that the carbonization of glucose does not lead to dense carbon of high graphite content but rather active charcoal like compounds with a high residual oxygen content. However, we only analyzed the electron concentrations of the pellet-based obtained electrides in this study.

### Determination of electron concentration

In the following section, we discuss results for quantitative determination of the electron concentration of C12A7 $e^-$ . In the literature several methods like DRUV/Vis spectroscopy, thermal analysis by TG, EPR spectroscopy, structural refinement

of X-ray/neutron diffraction data, electric conductivity measurements, iodometry are employed for this purpose. We herein describe difficulties in applicability of used analytical methods and their uncertainties as this is scarcely reported. Results for thermal analysis, EPR spectroscopy and Rietveld refinement of PXRD data are discussed for different solid reductants, DRUV/Vis analysis was mainly focused on graphite as solid reductant, followed by comparison of obtained quantitative results for different methods.

**Thermal analysis.** Matsuishi *et al.* first described using thermogravimetric analysis (TG) to determine the electron concentration in combination with DTA under 80% He/20% O<sub>2</sub> atmosphere.<sup>42,45,46</sup> The theoretical maximum mass uptake from [Ca<sub>24</sub>Al<sub>28</sub>O<sub>64</sub>]<sup>4+</sup>:4e $e^-$  (C12A7 $e^-$ ) to [Ca<sub>24</sub>Al<sub>28</sub>O<sub>64</sub>]<sup>4+</sup>:2O<sup>2-</sup> (C12A7) is 1.17 wt% and corresponds to an electron concentration of  $2.3 \times 10^{23} \text{ cm}^{-3}$ . Full oxygen uptake from [Ca<sub>24</sub>Al<sub>28</sub>O<sub>64</sub>]<sup>4+</sup>:4e $e^-$  (C12A7 $e^-$ ) to [Ca<sub>24</sub>Al<sub>28</sub>O<sub>64</sub>]<sup>4+</sup>:2O<sup>2-</sup> (C12A7) is reported to lead to a weight gain of 1.20 wt% from 573 to 1623 K while a maximum weight gain of 1.70 wt% is observed from 573 to 1048 K in the study of Matsuishi *et al.*<sup>42</sup> Trofymuk *et al.* report a slightly different behavior, the maximum mass uptake of 1.70 wt% is not reported, only the uptake of 1.2 wt%.<sup>46</sup> Combination of TG with DSC allows not only investigating changes in mass, additionally exo- and endothermic effects can be observed by DSC.

Fig. 3 shows results for DSC-TG experiments under synthetic air or N<sub>2</sub> atmosphere for (a) Ar and (b) Ar/H<sub>2</sub> plasma treated pure C12A7 and Ar/H<sub>2</sub> plasma treated C12A7 with (c) 20 wt% Al or (d) 3 wt% C (graphite) solid reductant addition. For (a) C12A7 plasma treated in Ar atmosphere a residual mass uptake of 0.5 and 0.2 wt% from 623 K to 1573 K and a maximum mass uptake of 0.7 and 0.4 wt% from 623 K to 1273 K can be observed for N<sub>2</sub> and synthetic air atmospheres respectively. The DSC curves for this sample show no clear signal. 95% Ar/5% H<sub>2</sub>

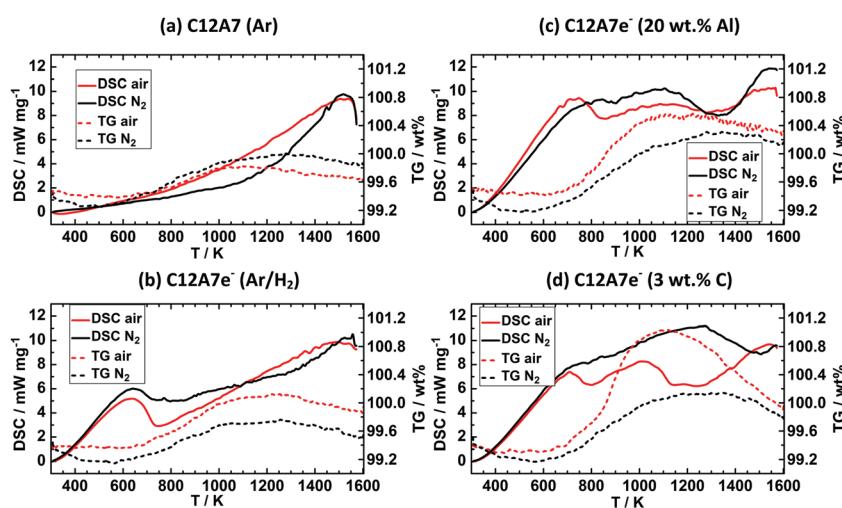

Fig. 3 DSC-TG experiments of the powders obtained after plasma treatment, (a) C12A7 (Ar), (b) C12A7 $e^-$  (95% Ar/5% H<sub>2</sub>), (c) C12A7 $e^-$  (20 wt% Al), (d) C12A7 $e^-$  (3 wt% C). Solid lines are respective DSC curves (exo. up) and dashed lines the TG curves. Black lines are experiments carried out under N<sub>2</sub> atmosphere, while red lines belong to experiments with synthetic dry air. The stronger mass increase indicated by TG between 800 and 1300 K under synthetic air indicates the presence of electrides in (b-d).

**Table 4** Electron concentrations  $N_e$  obtained by thermal analysis or DRUV/vis and normalized intensities  $I_N$  from EPR spectra for C12A7e<sup>-</sup> obtained from different solid reductants and from several graphite-based experiments. The value in square brackets for thermal analysis is the residual mass uptake in synthetic air used for calculating the electron concentration

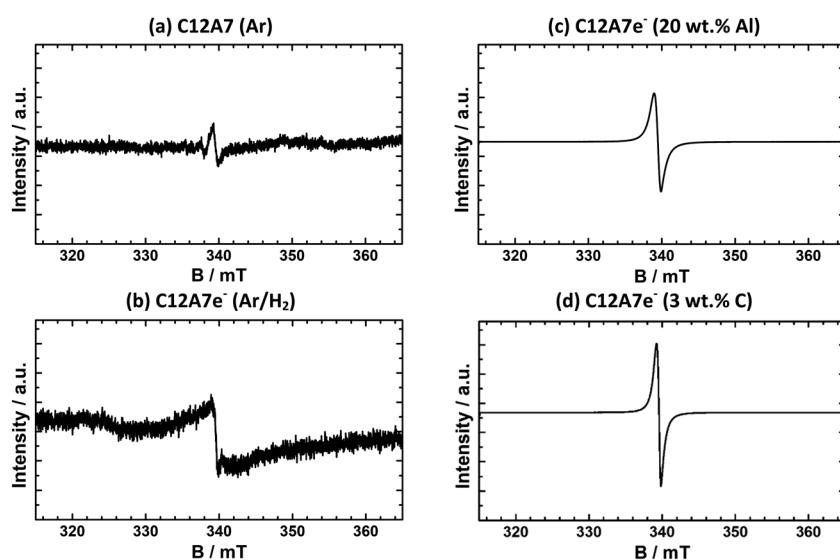

Sample	$N_e/10^{21} \text{ cm}^{-3}$ (thermal analysis)	$N_e/10^{21} \text{ cm}^{-3}$ (DRUV/vis)	$I_N/\text{a.u.}$ (EPR)
(a) C12A7 (Ar)	0.4 [0.2 wt%]	—	0.7
(b) C12A7e <sup>-</sup> (Ar/H <sub>2</sub> )	1.0 [0.5 wt%]	—	27.3
(c) C12A7e <sup>-</sup> (20 wt% Al)	1.5 [0.8 wt%]	—	2500
(d) C12A7e <sup>-</sup> (3 wt% C)	1.1 [0.5 wt%]	0.5	4630
(e) C12A7e <sup>-</sup> (3 wt% C)	—	1.2	4825
(f) C12A7e <sup>-</sup> (5 wt% C)	—	0.6	4018
(g) C12A7e <sup>-</sup> (3 wt% C)	—	0.3	2535
(h) C12A7e <sup>-</sup> (3 wt% C)	—	0.1	3458

treated C12A7 (b) showed a maximum mass uptake of 0.5 and 0.7 wt% and a residual mass uptake of 0.3 and 0.5 wt% for N<sub>2</sub> and synthetic air, respectively. Contrary to sample (a) an exothermic signal at about 700 K can be observed which is also reported by Trofymuk *et al.* and Matsuishi *et al.* which is correlated to oxidation of C12A7e<sup>-</sup> to C12A7 in literature.<sup>44,46</sup>

C12A7e<sup>-</sup> samples (c) and (d) based on solid reductant addition show residual mass uptakes of (c) 0.9 and 0.8 wt% and (d) 0.5 and 0.5 wt% with N<sub>2</sub> and synthetic air respectively, while the maximum mass uptakes are (c) 1.0 and 1.1 wt% and (d) 0.9 and 1.7 wt% with N<sub>2</sub> and synthetic air respectively. Both samples show two exothermic peaks with synthetic air at about 700 and 1200 K while under N<sub>2</sub> for both samples no clear exothermic peak at 700 K is observed and only for (c) a peak at about 1300 K can be identified. The peak at 700 K well agrees with literature values while the second signal is not described in the literature and no direct identification of the origin is possible.<sup>44,46</sup> Electron concentrations for all samples were

calculated based on the residual mass uptake under synthetic air and are summarized in Table 4. The mass loss from the maximum mass at about 1050 to 1200 K to the residual mass at about 1650 K is described by Trofymuk *et al.* and Matsuishi *et al.* as an incorporation from oxygen species such as O<sup>-</sup> and (O<sub>2</sub>)<sup>-</sup>.<sup>44,46</sup> However, we cannot explain the differences observed between N<sub>2</sub> and synthetic air based on these assumptions. For pure N<sub>2</sub> this mass uptake should not be observed. In reproducibility tests the same sample was tested four times under the respective conditions (N<sub>2</sub> or synthetic air). The reproducibility tests indicated only an absolute accuracy of  $\pm 0.25$  wt% in determination of the residual mass uptake. Based on this level of accuracy, in general electron concentrations based on TG experiments should be treated with care as the standard deviation corresponds already to an electron concentration of  $0.5 \times 10^{23} \text{ cm}^{-3}$ . This absolute value already corresponds to properties and electron concentration of a semiconducting electride characterized by a green color which is not the case for (a) showing a white color despite a calculated  $N_e$  value of  $0.4 \times 10^{23} \text{ cm}^{-3}$  from TG analysis.

**Electron paramagnetic spectroscopy (EPR).** Determination of electron concentrations and study of the presence of localized electrons by EPR was described by Matsuishi *et al.* while it was only possible to quantitatively determine the concentration to levels of  $N_e = 5 \times 10^{19} \text{ cm}^{-3}$ .<sup>5</sup> This value accounts for semiconducting C12A7e<sup>-</sup> where all electrons are still localized. With increasing electron concentration C12A7e<sup>-</sup> becomes conductive and electrons delocalized which was found in EPR spectra by observation of Dysonian peak shapes.<sup>43</sup> The g-factors for the signal observed in the literature are reported to be 1.994<sup>4,5</sup> and 1.998.<sup>43</sup> In Fig. 4 EPR spectra for C12A7 and C12A7e<sup>-</sup> prepared by different solid reductants and treatment atmospheres are shown. The signal for C12A7 treated under Ar atmosphere is increased by 5000 times and the one for C12A7e<sup>-</sup> treated under

**Fig. 4** EPR spectra of powders after plasma treatment (a) C12A7 (Ar), (b) C12A7e<sup>-</sup> (95% Ar/5% H<sub>2</sub>), (c) C12A7e<sup>-</sup> (20 wt% Al), (d) C12A7e<sup>-</sup> (3 wt% C). For all samples, a signal appears at about 340 mT showing the presence of located electrons in the sample. Intensity scale is not the same for all samples, (a and b) are zoomed  $\sim 5000$  and  $\sim 100$  times, respectively.

95% Ar/5% H<sub>2</sub> atmosphere is increased by 100 times for visualization. All four spectra show a signal at  $B = 339.5$  mT with *g*-factors of (a) 1.9962, (b) 1.9960, (c) 1.9966 and (d) 1.9966. The values for the *g* factors match the ones reported in the literature. From this result, we can conclude that plasma treatment according to the new method results in the formation of electride materials. However, all spectra show an isotropic Lorentzian peak shape and not a Dysonian peak shape as reported in the literature for metallic conductive C12A7e<sup>-</sup><sup>43</sup>. This indicates presence of semiconducting C12A7e<sup>-</sup> by using aluminum or graphite as solid reductants and a much smaller number of electrons for C12A7e<sup>-</sup> obtained without solid reductant addition using 95% Ar/5% H<sub>2</sub> atmosphere.

For a qualitative comparison of the EPR spectra, normalized intensities  $I_N$  of peaks of integrated first derivative spectra were determined by integration of the peak area and normalization with eqn (1). The graphite-based electride sample shown (d) has an  $I_N = 4630$  and the aluminum-based (c) of  $I_N = 2500$ . For all synthesized graphite-based C12A7e<sup>-</sup> samples by the same synthesis method, values for the normalized intensity range from  $I_N = 2540$  to 4800. Nevertheless, EPR analysis of samples clearly confirms the presence of C12A7e<sup>-</sup> by *g*-factor analysis and comparison with literature results. Furthermore, the  $I_N$  as listed in Table 4 show a clear correlation of the electron concentration in comparison of samples (a) to (d). From these results, we can conclude that in order to achieve a high electron concentration, the use of gaseous reductants (95% Ar/5% H<sub>2</sub>) is insufficient and solid reductants are required. A comparison of the results for electron concentration determination by EPR with the other applied methods is done in Section 3.2.5.

**Diffuse reflectance UV-vis spectroscopy (DRUV/vis).** DRUV/vis is reported to be a suitable method for determination of electron concentrations in several studies.<sup>5,42-44</sup> Matsuishi *et al.* first reported the relationship in eqn (3) for the Kubelka–Munk transformed spectra to determine the electron concentration in C12A7e<sup>-</sup>.<sup>5</sup> A peak position at 2.83 eV is assigned to an electron concentration of  $N_e = 1 \times 10^{18} \text{ cm}^{-3}$ , while a shift to lower energies and increased intensity is reported<sup>5</sup> with increasing number of electrons as shown in Fig. 5 for different C12A7e<sup>-</sup> samples prepared using graphite as solid reductant. The dashed line symbolizes a mixture of C12A7 with graphitic carbon species obtained from carbonization of a C12A7 precursor, as discussed for the glucose-based approach before, showing no specific peak in the region of interest. Solid lines represent results for different sample batches obtained by using graphite as solid reductant.

In Table 4 electron concentrations obtained from DRUV/Vis for different solid reductants and different graphite-based sample batches are summarized together with measures from other methods. All graphite-based samples in Fig. 5 were synthesized by plasma treatment under 95% Ar/5% H<sub>2</sub> atmosphere until homogeneous melting balls were observed. The resulting powders all displayed similar appearance in color after grinding. For the determination of the electron concentration with eqn (3) the position of the maximum peak was determined (in order to do so this was done by first smoothing

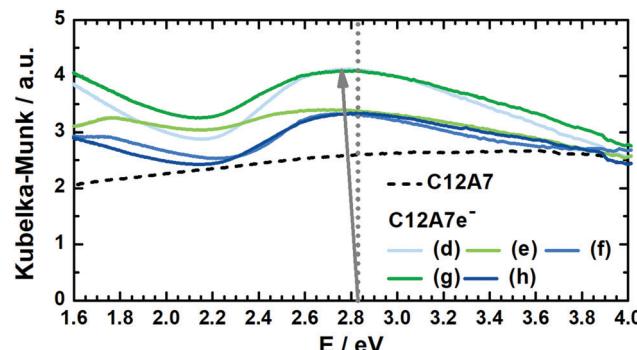

Fig. 5 Kubelka–Munk transformed DRUV-vis spectra for several graphite-based C12A7e<sup>-</sup> sample batches (solid) and carbonized C12A7 precursor sample (dashed) for comparison. According to Matsuishi *et al.*, the dotted line at 2.83 eV corresponds to the absorption peak maximum for an electron concentration of  $N_e = 1 \times 10^{18} \text{ cm}^{-3}$ .<sup>5</sup> With increasing  $N_e$  the maximum shifts towards lower energy values, as illustrated with the arrow, which can be used for estimating  $N_e$ .

the data with FFT filter and second formation of the first derivative to determine the maximum). Smoothing of the data was done as the noise level of the spectra led to erratic determination of the maximum position, *i.e.* values with higher electron concentrations than stoichiometrically possible were observed. The error based on the accuracy of the DRUV/vis measurement in determining the maximum position is estimated as  $\pm 0.02$  eV. This systematic accuracy results in a high relative error in the determination of the respective electron concentration, *e.g.* sample (d) has an electron concentration of  $N_e = 0.5 \times 10^{21} \text{ cm}^{-3}$  with the error of  $\pm 0.02$  eV the calculated maximum and minimum values are  $N_e = 0.3 \times 10^{21} \text{ cm}^{-3}$  and  $N_e = 0.6 \times 10^{21} \text{ cm}^{-3}$  which corresponds to a relative error of roughly 50%. Our suggestion is that in respect of this high uncertainty values should be rather discussed qualitatively. An indication of the conductivity properties of C12A7e<sup>-</sup>, *i.e.* insulator, semi-conductor or conductor is possible with literature data. In comparison with studies by the group of Hosono, we conclude that all 3 wt% graphite-based C12A7e<sup>-</sup> are semiconductors with properties close to metallic conductors.<sup>5,42-44</sup> However, the results obtained by the method of DRUV/vis itself should be discussed with caution, as eqn (3) in combination with the method-inherent relative error based on experimental data can lead to difficulties in highly accurate quantitative determination of the electron concentration.

**X-ray powder diffraction (PXRD).** Rietveld refinement of PXRDs allows obtaining information about lattice parameters, atomic parameters of the present crystallographic structure based on an initial structural model and information about phase fractions. In Fig. 6 results of Rietveld refinement of powders from (a) Ar and (b) Ar/H<sub>2</sub> plasma treated pure C12A7 and Ar/H<sub>2</sub> plasma treated C12A7 with (c) 20 wt% Al or (d) 3 wt% C (graphite) solid reductant addition is shown. For refinements different initial structural models from Sakakura *et al.*, Palacios *et al.* and Boysen *et al.* were tested.<sup>10,11,41</sup> Though none of the models showed an improved refinement. Compared to other techniques (see above) to determine the electron concentration,

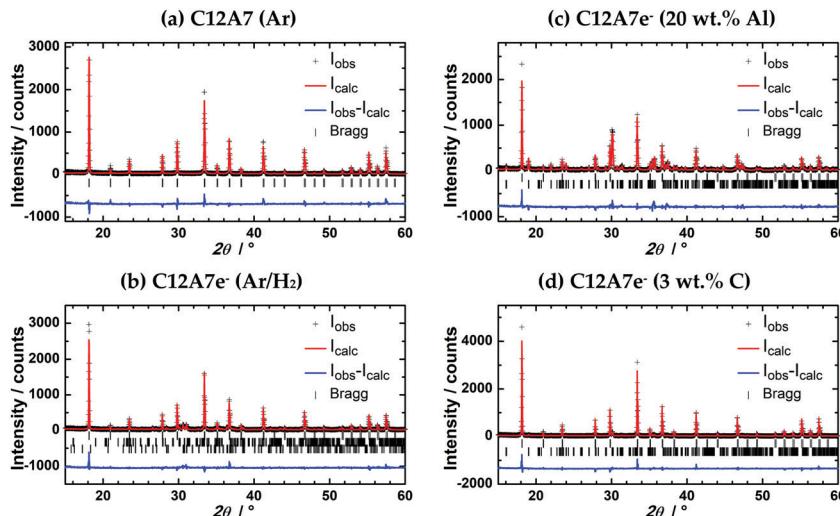

Fig. 6 Rietveld refinement of PXRDs of powders after plasma treatment, (a) C12A7 (Ar); (b) C12A7e<sup>-</sup> (95% Ar/5% H<sub>2</sub>); (c) C12A7e<sup>-</sup> (20 wt% Al); (d) C12A7e<sup>-</sup> (3 wt% C). PXRD were measured with  $\lambda_1 = 154.06$  pm,  $\lambda_2 = 154.44$  pm,  $\lambda_1/\lambda_2 = 2$ . Parameters obtained from Rietveld refinement are listed in Table 3. First row of Bragg markers corresponds to C12A7e<sup>-</sup>, second row to CA and third row to C5A3 phases.

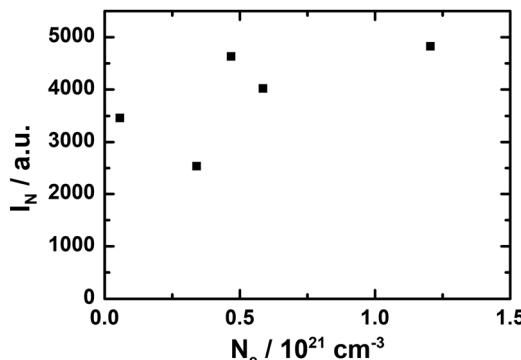

results shown in this work are based on the model by Sakakura *et al.* as it is from the same group of Hosono as the other methods. The measured PXRDs were refined regarding their profile and lattice parameters while atomic parameters were kept fixed according to the initial model. An inclusion into the refinement of the atomic parameters led to unstable refinements and was therefore discarded.

Lattice parameters obtained from Rietveld refinement together with phase fractions are summarized in Table 3. In studies by Palacios *et al.* and Kanbara *et al.* an increase of the lattice parameter  $a$  for increased electron concentrations is reported.<sup>10,29,40</sup> Palacios *et al.* reported an increase from 1197.113(8) pm to 1199.580(7) pm and 1198.215(9) pm to 1199.522(2) pm from C12A7 to black C12A7e<sup>-</sup>.<sup>10,40</sup> Kanbara *et al.* reported an increase from 1198.6 pm for C12A7 to 1199.9 pm.<sup>29</sup> From our results we cannot confirm this behavior.  $a$  of pure (a) C12A7 treated in Ar is about 1 pm larger than the literature values. This increase might be caused due to the rapid heating and cooling during the plasma synthesis or the expected structural distortion compared to the electride structure caused by the occupancy of two cages by O<sup>2-</sup> for C12A7 instead of four cages by e<sup>-</sup> for C12A7e<sup>-</sup>.<sup>13</sup> Though comparing (b) C12A7e<sup>-</sup> treated in 95% Ar/5% H<sub>2</sub> atmosphere with solid reductant synthesized (c and d) C12A7e<sup>-</sup> we do see an increase of  $a$  from 1199.13(2) pm to (c) 1199.942(19) pm or (d) 1199.661(19) pm showing the identical behavior for  $a$  as reported in the literature for an increasing electron concentration. However, we cannot exactly explain why the values of  $a$  for the samples (b) and (d) are significantly smaller compared to sample (a). As the complete refinement also for atomic parameters was not possible and the lattice parameters do not completely follow the literature reported trends, we believe it is fair to conclude that it is doubtful whether Rietveld refinement of powder diffraction data obtained on standard diffraction instruments is suitable to analyze the electron

concentration in mayenite electrides; however the situation concerning data quality may become different when using synchrotron beamline derived PXRD data. We have reason to believe that the complexity of the structure, especially of the mixed occupancy of the cage anion position, may make additional studies of the materials by single crystal XRD for refinement of atomic positions necessary.

**Summary challenges in determining exact values for the electron concentration in mayenite electrides.** Quantitative determination of electron concentrations in C12A7e<sup>-</sup> was found to be a challenging topic. Thermal analysis, EPR spectroscopy, DRUV/Vis spectroscopy and Rietveld refinement of PXRD were tested to quantitatively access the electron concentration as reported in the literature. Compared results for selected samples are summarized in Table 4 for thermal analysis, DRUV/Vis and EPR spectroscopy. EPR spectroscopy clearly confirmed the successful synthesis of mayenite electride materials and a clear correlation for the samples (a)–(d) in electron concentration could be demonstrated. However, based on our results we suggest that EPR spectra have to be interpreted with caution, as sufficient quantitative information is difficult to obtain, compared to reports in the literature by Matsuishi *et al.*<sup>5</sup> By taking information derived from EPR analysis and thermal analysis for samples (a–d) at maximum qualitative correlations could be concluded.  $N_e$  values derived from TG analysis show even for (a) C12A7 an electron concentration of  $0.9 \times 10^{21}$  cm<sup>-3</sup> which would be characteristic to a semiconducting or metallic conducting mayenite electride as reported in the literature studies.<sup>42,45,46</sup> The color of such C12A7e<sup>-</sup> should be dark green to black, though sample (a) is a white powder, characteristic for an insulating material. In Fig. 7 a correlation of results from DRUV/vis and EPR for graphite-based C12A7e<sup>-</sup> shows no direct unambiguous relationship between the values. Based on these results, we conclude that it remains difficult to quantitatively investigate the electron

**Fig. 7** Correlation analysis for electron concentration  $N_e$  values determined by DRUV/vis analysis and corresponding normalized  $I_N$  of the absorption EPR spectra. A linear relationship as expected cannot be seen reliably between  $N_e$  and  $I_N$ .

concentration of the material on a routine basis with methods employed in this study. Only a combination of various methods can deliver a picture that reveals the electronic nature of the mayenite electrides.

## Conclusions

In the present work we report a new, scalable and facile method to synthesize mayenite-based electrides ( $\text{C}12\text{A}7\text{e}^-$ ). Plasma treatment of mixtures of mayenite with aluminum or graphite as solid reductants, which are similar applied to getter materials, in Ar or Ar/H<sub>2</sub> atmosphere lead to the formation of mayenite based electrides. The solid reductant has a major influence on the structural composition of the product composite: aluminum leads to enhanced formation of krotite as a secondary phase, which can be prevented by using graphite as reductant. Thus, using a plasma treatment of a C12A7/graphite mixture was found as the optimum to achieve high electron concentrations while achieving a tolerable secondary phase amount. The analysis of the electron concentration was achieved by EPR-, DRUV/vis spectroscopy, Rietveld refinement of PXRD and DSC-TG under oxidizing atmospheres. However, in a critical revision we found that data obtained from these methods must be taken with caution and may in certain cases, especially if only a single analytical method is employed, be limited to obtaining only qualitative information about the electron concentration in mayenite electrides. Furthermore, preparation of multiple samples might be required to obtain statistical meaningful characterization results for the electron concentration. Based on our characterization results and in comparison with the relevant literature we conclude that the plasma-based approach provides a suitable synthesis of semiconducting close to metallic conducting electride materials. Furthermore, plasma treatment in reductive atmospheres, *i.e.* 95% Ar/5% H<sub>2</sub> appears to be insufficient to obtain high electron concentrations. In this case, the use of solid reductants is recommended for the latter purpose. With the presented scalable plasma-based preparation method, mayenite and related

electrides may find a broader range of applications in heterogeneous catalysis.
