Nanostructured electroless Ni deposited SnO₂ for solar hydrogen production†

Priyanka N. Birla,^a Sudhir Arbuji,^a Ratna Chauhan,^b Manish Shinde,^a Sunit Rane,^a Suresh Gosavi^b and Bharat Kale^{a,c}

Herein, Ni-decorated SnO₂ (Ni@SnO₂) nanostructures have been synthesized using SnO₂ as a matrix *via* a simple electroless deposition method for the generation of hydrogen, a potent near-future fuel. XRD analysis confirmed the generation of rutile SnO₂ in Ni@SnO₂. FESEM and FETEM imaging exhibited the formation of SnO₂ nanoparticles with a size of 10–50 nm, which are deposited with Ni nanoparticles (5–7 nm) and intermittent films (thickness 1–2 nm). The associated EDS elemental mapping validated Ni deposition on the surface of the SnO₂ nanoparticles, further supplemented by FTIR, Raman and XPS analysis. Slight red shifts in the band gaps of the Ni@SnO₂ nanostructures (in the range of 3.53–3.65 eV) compared to the pristine SnO₂ nanoparticles (3.72 eV) were observed. Also, intensity quenching of the band gap and associated defect peaks were observed in PL analysis. The Ni@SnO₂ nanostructures were used as photocatalysts and exhibited proficient hydrogen evolution. Among the samples, the 0.3 wt% Ni@SnO₂ nanostructures showed the greatest hydrogen evolution, *i.e.*, ~50 μmol g⁻¹ h⁻¹ under visible light irradiation *versus* pristine SnO₂ (8.5 μmol g⁻¹ h⁻¹) owing to the enhanced density of active sites and effective charge separation. It is noteworthy that the hydrogen evolution is much better as compared to earlier reports of Pt-doped-SnO₂ based materials.

Introduction

Fuels play a vital role in the progressive industrialized economy, in which an enormous amount of energy is required for various processes such as heating, lighting, transportation, power generation, production, *etc.* Until the last few decades, the world relied heavily on fossil fuels. In the contemporary scenario, depletion of perishable energy sources as well as environmental issues such as global warming have arisen, and the world is facing an energy crisis that requires significant attention. Researchers are focusing on environmentally friendly concrete technologies for energy generation using various sustainable sources with assured energy security.

When the various sustainable energy fuel options are scrutinized, hydrogen is found to be the apt alternative, although it is in its infancy in terms of development of the technology (hydrogen economy) owing to the bottlenecks related to its

safe and efficient storage and delivery.¹ Its vast energy capacity, as well as its relatively clean and energy-efficient nature, make hydrogen a proficient energy carrier.² As 8% of overall energy demand is predicted to be fulfilled *via* hydrogen by the year 2050, a need for the development of hydrogen production methods with near-zero greenhouse gas emissions has arisen.³

At present, the overall demand of hydrogen is overwhelmingly (>95% of total demand) satisfied by the steam reforming process or the partial oxidation of hydrocarbons with the inevitable generation of carbon dioxide.⁴ As an alternative, water splitting is a relatively greener method of hydrogen production carried out using techniques such as thermochemical,⁵ photo-fermentative,³ and photo-electrolytical⁶ methods *via* exposure to thermal, photo- or photo-electrical radiation. However, these techniques are either slow or energy intensive. One technology for H₂ production is photocatalytic water splitting; it entails photonic energy, which is considered to be the most abundant energy resource on Earth.⁷

In this context, the most suitable water splitting methodology is based on catalysts known as semiconductor photocatalysts that are activated under electromagnetic (solar) radiation, which split the water molecule into hydrogen and oxygen through the process known as photocatalysis.^{1,8} Such photocatalytic water splitting leads to H₂ evolution on the photocatalyst surface *via* its interplay with water molecules, culminating in the generation of strong oxidizing mediators

such as hydroxyl and superoxide radicals sans any costly or advanced reaction set-up.⁹

Considering the importance of photocatalytic water splitting, various types of photocatalysts and their combinations need to be reviewed for evaluation of their pros and cons. To date, numerous photocatalysts have been employed for hydrogen production, such as widely used conventional semiconductor metal oxides like TiO₂,¹⁰ and ZnO,¹¹ as well as other materials including WO₃,¹² BiVO₄,^{13,14} BiOBr,¹⁵ Bi₂WO₆,¹⁶ Ag₂S,¹⁷ Ag₃PO₄,¹⁸ AgBr,¹⁹ Ag₃VO₄,²⁰ CdS,²¹ P/YPO₄,²² metal-organic frameworks (MOFs),²³ SnO₂,²⁴ *etc.* Among these materials, tin dioxide (SnO₂), which has several polymorphs, is an earth-abundant, non-toxic, and chemically stable n-type semiconductor material with a wide direct band gap (3.6 eV), reasonable optical transparency, and significant electron mobility; therefore, it has been extensively exploited in sensors, solar cells, supercapacitors, Li-ion lithium batteries and photocatalysis.²⁵ However, as a photocatalyst, it suffers from its wide band gap, which impedes its response to visible light, and its notorious photogenerated charge carrier recombination; these have resulted in there being a relatively small number of reports on SnO₂-based photocatalytic water splitting studies.²⁶

These intrinsic downsides can be overcome by implementing strategies such as band gap engineering, enhanced charge-carrier separation, and transmission and swift redox reaction through surface modification *via* exhaustive tactics including composite photocatalyst construction and tuning of the material preparation protocols for morphology control, which have been adopted to design novel SnO₂-based photocatalysts.^{24,27,28} Various SnO₂-based composite photocatalyst preparation techniques, namely, hydro/solvothermal,²⁹ co-precipitation,³⁰ sol-gel,³¹ polyol,³² auto-combustion³³ and microwave methods,³⁴ among others, have been reported. Among these methods, co-precipitation synthesis exhibits benefits, including low-temperature processing, improved safety, economic advantages, and facilitated mass production.³⁵ SnO₂ composite formation can be achieved through the introduction of a metal/nonmetal combination for appropriate surface modification.³⁶ In this direction, co-catalyst-based semiconductor composite photocatalytic systems such as Pt@SnO₂,^{37,38} SnO₂/Pt/In₂O₃,³⁹ Pt@SnO₂/graphene,⁴⁰ Pt/SnO₂/GNs,⁴¹ TiO₂/Pt/SnO₂,⁴² and Au/Pt/SnO₂⁴³ have been reported for photocatalytic applications. However, such noble-metal-based photocatalytic materials can prove to be costly, hampering their industrial applicability. Simultaneously, the need to reduce environmental pollution and the photocatalyst production process cost also need to be taken into account.²⁴

Nickel has been recognized as a strong substitute for noble metal co-catalysts owing to its renowned catalytic behaviour in numerous chemical reactions in industry. In this context, Ni and NiO have been loaded over the surface of SnO₂ to enhance their properties.^{26,35} For Ni@SnO₂ nanostructures, various synthesis techniques, such as chemical reduction,⁴⁴ solvothermal treatment,³⁵ photoreduction,⁴⁵ and wet and chemical reduction,⁴⁴ have been studied by researchers. It is worth

noting that electroless plating, although typically executed for various metal-based surface microlayer coatings on workpieces, has surprisingly arisen as a substitute for constructing surface-loaded nano-assemblies of different materials.⁴⁶ It is an autocatalytic surface coating process in which the metal to be deposited on the surface of the nanomaterials can be used in a cost-effective manner due to the low concentration requirements, control of the phase and morphology formation for large surface areas, *etc.*, and has become a trending theme in the nano-assembly of metal-loaded semiconductor composites.^{47,48} This technique, which is also known as electroless loading, is mouldable with respect to the substrates being metallized and can deposit metallic nanoparticles or films on materials in the solid, liquid or gaseous states with different chemical forms, sizes and shapes.⁴⁹ It can generate nanoparticles having varied morphologies such as nanotubes, nanoparticles, nanowires, and ultrathin films, *etc.*, on the surface of the host materials by using a simple solution chemistry approach.⁵⁰ To the best of our knowledge, electroless Ni loading over the surface of an SnO₂ nanostructure has not been reported so far.

In this context, Ni@SnO₂ nanostructure photocatalysts have been prepared *via* the coprecipitation of SnO₂ nanoparticles followed by Ni loading using the electroless plating technique. The study of the effect of Ni loading over the surface of the SnO₂ nanoparticles and their photocatalytic water splitting leading to hydrogen production has been accomplished. The overall results established the efficacy of hydrogen production, revealing its utility as a scalable and cost-effective technique.

Materials and methods

Materials

For synthesis of the SnO₂ nanopowders, the required precursors, namely, stannous chloride dihydrate (SnCl₂·2H₂O), methanol, and NH₄OH, were procured from Qualigens and SRL, India, respectively. Electroless nickel loading was performed using a commercial electrochemical bath that was procured from Grauer & Weil (India) Limited, which was composed of various solutions for cleaning, mild etching, pre-activation, activation and finally Ni loading. For the acid wash after the mild etching step, H₂SO₄ (98% conc., SRL chemicals, India) was diluted with deionized water to prepare a 10% sulphuric acid solution.

Material preparation

Synthesis of SnO₂ nanopowders . A facile co-precipitation method was employed for the preparation of the SnO₂ nanopowders. In this process, 0.1 M stannous chloride dihydrate (SnCl₂·2H₂O) was dissolved in a 4 : 1 v/v MeOH : distilled water mixture. Upon complete dissolution, liquor ammonia was added to obtain a pH of 8, leading to the formation of an off-white coloured precipitate, which was washed with distilled water until neutralization under centrifugation, dried and then

calcined at 650 °C for 6 h and used as-is for further characterization and Ni loading.

Autocatalytic Ni deposition on the SnO₂ nanopowder surface. The details of Ni bath preparation process were provided in our previous work.⁴⁸ The electroless nickel loading process entailed a number of steps as detailed in Table T1 (ESI†) with continuous stirring. Centrifugation was carried out at the conclusion of each step. Fig. 1 shows all of the procedures involved collectively in the synthesis of SnO₂ nanoparticles and autocatalytic deposition of nickel on their surfaces. The SnO₂ nanoparticle surfaces were normally cleaned in three steps; using a cleaning solution that was kept at 60 °C for 10 min, followed by treatment with mild etching and acid solutions for 4 and 2 min, respectively, and centrifugation was carried out after each stage was finished with a water wash. After cleaning, the surface of the SnO₂ nanopowder was treated with a pre-activator solution for 2 min. However, after this step, there was no water rinsing.

By exposing the preactivated SnO₂ nanoparticles to activator and post-activator solutions for 5 min each, followed by rinsing them with water, the powder became surface activated. The surface-activated SnO₂ nanopowder was then exposed to Ni loading for 15 min by placing it in a Ni bath that was kept at a pH of 5.2 and a temperature of 85–90 °C (Fig. 1). The surface-activated SnO₂ nanoparticles were subjected to electroless Ni baths at different concentrations to adjust the Ni wt.% loading. The resulting samples were then utilized for photocatalytic water splitting (Table 1).

Characterization techniques

Crystalline behaviour study of the Ni@SnO₂ nanostructures was accomplished using powder X-ray diffraction (XRD, Rigaku MiniFlex 600, Cu-Kα1 radiation source of wavelength 1.54 Å) method. PHI Versa Probe XPS instrument employed for X-ray photoelectron spectroscopy (XPS) assisted the elemental compositional analysis of the pristine SnO₂ and 0.3% Ni@SnO₂ samples. The inductively coupled plasma optical emission spectroscopy (ICP-OES) technique was employed to confirm

Table 1 Electroless Ni bath composition for variable Ni wt% loading over SnO₂ nanoparticles

Sr. no.	Sample code (Ni wt%)	Nickel salt solution (mL)	Reducing agent solution (mL)	Calculated % Ni loading concentration
1	Pristine SnO ₂	0	0	0
2	0.1%Ni@SnO ₂	0.2	0.374	0.1
3	0.2%Ni@SnO ₂	0.4	0.748	0.2
4	0.3%Ni@SnO ₂	0.6	1.112	0.3
5	0.4%Ni@SnO ₂	0.8	1.496	0.4
6	0.5%Ni@SnO ₂	1.0	1.870	0.5

the Ni concentration of the synthesized products using a Spectroblue, Amtek. For these measurements, a typical sample (200 mg) was digested (in conc. HNO₃ (4 mL) and 30% H₂O₂ (1 mL)) in a microwave, and then diluted to 50 mL. The resultant solution was filtered and run through the calibration curve. A Renishaw Invia Raman microscope equipped with a 532 nm laser was utilized to study the Raman spectra of the Pristine-SnO₂ and Ni@SnO₂ nanostructure samples. Room temperature diffuse reflectance UV-visible absorbance spectra (UV-DRS) of the prepared materials were obtained in the range of 200–800 nm using a PerkinElmer LAMBDA 950 UV-VIS-NIR spectrophotometer. Photoluminescence (PL) emission spectra of the as-synthesised nanostructures were obtained using a Shimadzu (RF5301PC) spectrofluorometer at an excitation wavelength of 350 nm.

An IRAffinity-1S 01130 Shimadzu spectrometer was exploited for measuring Fourier transform infrared (FTIR) spectra between 400 and 4000 cm⁻¹. Morphological and microstructural investigations were performed using field emission scanning electron microscopy (FESEM, FEI NOVA NANOSEM 450) and field emission transmission electron microscopy (FETEM by JEOL, JEM-2200FS). For typical FETEM analysis, the test sample was carefully prepared by dispersing the sample powder in ethanol and then drop-casting it onto a carbon-coated grid. To obtain high imaging and spatial resolution with chemical mapping of the material, scanning trans-

Fig. 1 Process schematic for the synthesis of SnO₂ nanoparticles and their electroless loading with Ni.

mission electron microscopy (STEM) in bright field (BF) mode equipped with energy dispersive X-ray spectroscopy (EDS) coupled elemental mapping using a JEOL JEM2200FS operated at 200 kV was employed. The samples' porosity and surface area were determined using Brunauer–Emmett–Teller analysis (BET: Quantachrome NOVA touch LX1).

Photocatalytic hydrogen generation

Photocatalytic hydrogen generation from water was accomplished using a photocatalytic reactor set-up consisting of a total 100 mL airtight cylindrical quartz photochemical reactor with an attached cooling jacket for water circulation. A solar simulator (CEL-NP2000) with AM 1.5 G illumination (100 mW cm^{-2}) and a hood fan to disperse surplus heat was the illumination source. A standard photocatalytic experiment involved dispersing 20 mg of the photocatalyst in 40 mL of an aqueous solution mixture containing 20% methanol (v/v). The 60 mL open space of the photoreactor was sealed with a rubber septum, and the catalyst was dispersed uniformly *via* ultrasonication for 5 min. The resultant dispersion was purged with ultra-high purity (UHP-99.999%) nitrogen gas in order to eliminate dissolved oxygen from the solution and all the gases from the reactor's headspace. Gas chromatography (GC) with a thermal conductivity detector (Shimadzu GC-2014c; Ar carrier gas and molecular sieve-5 Å column) was employed for gas examination in the reactor's free space both before and after it was exposed to sunlight. At intervals of fifteen minutes, the reactor's hydrogen gas yield was measured by collecting the gas in the syringe and feeding it into the GC equipment.

Photoconductivity studies

A Keithley source meter (2450) was used for electrical measurement of pristine SnO_2 and Ni@SnO_2 nanostructure samples. A Class ABA Solar Simulator was used for white light illumination with a power density of 12 mW cm^{-2} .

Electrochemical studies

A CH 660C electrochemical analyzer (CH Instruments, Shanghai, China) with two electrodes was employed for the electrochemical impedance spectroscopy (EIS) study. Pt and the Ni@SnO_2 nanostructures played the roles of counter and working electrodes, respectively. Electrochemical impedance spectroscopy (EIS) with a 10 mV alternating signal was used to examine the electron transport parameters in the 10^{-2} – 10^5 Hz frequency range.

Results and discussion

XRD

The phase purity and crystallinity of the as-synthesized pristine SnO_2 and Ni@SnO_2 nanostructures were established using X-ray diffraction, and the results are shown in Fig. 2. The *prima-facie* XRD reflections of the pristine SnO_2 and Ni@SnO_2 nanostructures show that the prepared materials were well matched with JCPDS number 41-1445 with the peaks exhibit-

Fig. 2 X-ray diffractograms of the prepared pristine SnO_2 and Ni@SnO_2 nanostructure samples.

ing reasonable similitude with rutile-phase tetragonal SnO_2 . The observed peaks at 2θ values of 26.57, 33.89, 37.90, 38.06, 51.79, 54.74, 57.92, 61.92, 64.76, 66.05, 71.36 and 78.79° were in good agreement with the corresponding crystalline [110], [101], [200], [111], [211], [220], [002], [310], [112], [301], [202] and [321] planes.^{51,52}

The substantial broadening of peaks observed in all the samples is an indication of the nanoscale nature of all the samples.⁵³ Diffraction peaks due to Ni are not observed in any of the samples due to the low Ni loading percentage, which is lower than the detection limit of XRD, and probably due to formation of even smaller Ni nanoparticles/surface coatings on the SnO_2 nanoparticles.

X-ray photoelectron spectroscopy

Analysis of the surface chemical and electronic states of the pristine SnO_2 and Ni@SnO_2 nanostructure samples was carried out using the XPS technique (Fig. 3). The XPS survey spectra of both pristine SnO_2 and the 0.3% Ni@SnO_2 nanostructure sample revealed the presence of characteristic peaks due to the elements Sn and O, with an additional peak assigned to Ni in the 0.3% Ni@SnO_2 nanostructure sample (Fig. 3a). Further insights into the composition were obtained

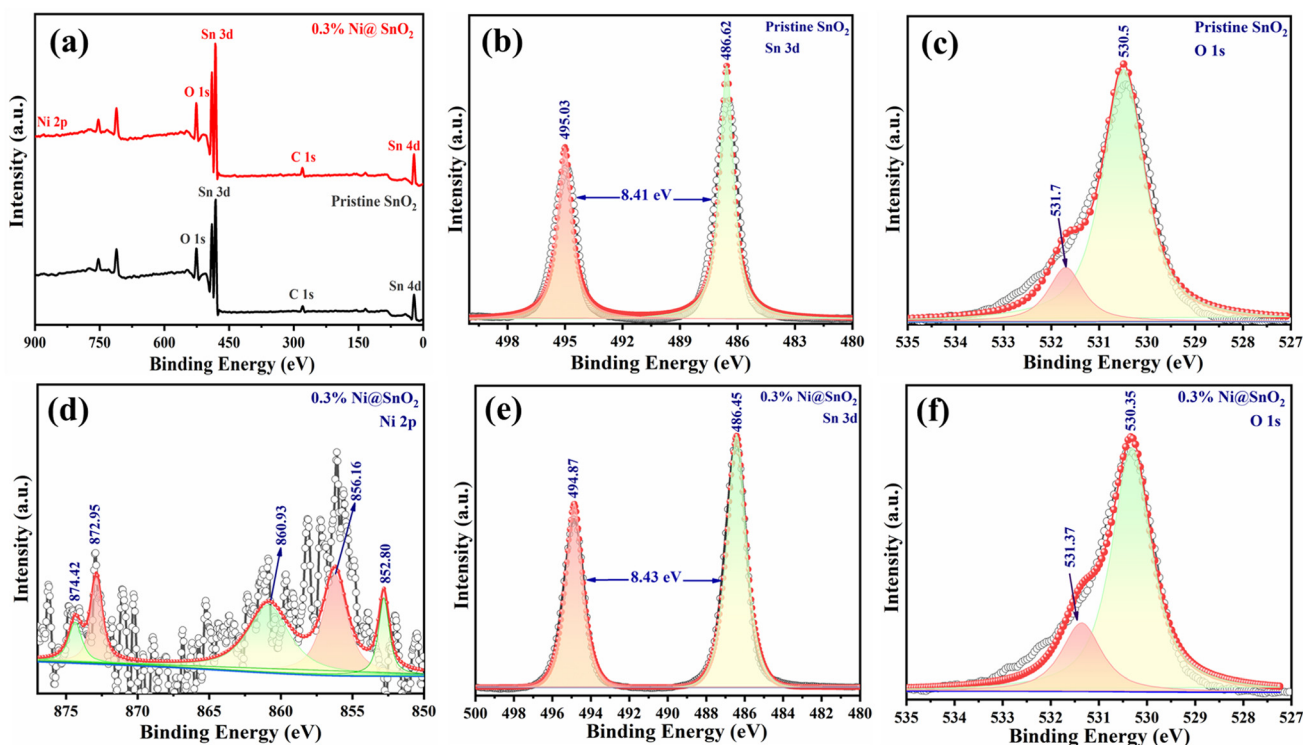

Fig. 3 XPS spectra of pristine SnO₂ and 0.3% Ni@SnO₂ nanostructure samples. (a) Survey scan for both samples, and deconvoluted high-resolution scans corresponding to the elements (b) Sn 3d and (c) O 1s for Pristine SnO₂ and (d) Ni 2p, (e) Sn 3d and (f) O 1s for the 0.3% Ni@SnO₂ nanostructure.

from the high-resolution scans for the respective elements. The high-resolution scans corresponding to Sn 3d (Fig. 3b and e) displayed splitting of peaks into doublets attributable to Sn 3d_{5/2} and Sn 3d_{3/2} with values of 486.62 eV and 495.03 eV and 486.45 eV and 494.87 eV for the pristine SnO₂ and 0.3% Ni@SnO₂ nanostructure sample, respectively.^{54,55}

The O 1s peak was observed to be fragmented into an intense peak at 530.50 and 530.35 eV for pristine SnO₂ and 0.3%Ni@SnO₂ nanostructure samples respectively as shown in Fig. 3c and f, which could be assigned to O²⁻ bonded with Sn⁴⁺. Another peak at 531.37 eV in both these samples could be ascribed to defect sites or vacancies.⁵⁵

The high-resolution scan for Ni of the 0.3%Ni@SnO₂ nanostructure sample revealed multiple peaks (Fig. 3d). The presence of peaks at 872.95 eV and 856.16 eV were credited to Ni 2p splitting into Ni 2p_{1/2} and Ni 2p_{3/2} orbitals, respectively. The peaks at 860.93 and 874.42 eV are due to the presence of satellite peaks. The generation of zerovalent Ni (Ni⁰) was confirmed by the existence of a peak at 852.8 eV attributable to the reduction of the Ni precursor during electroless loading process. Moreover, as a hydrogen adsorption site, the presence of Ni⁰ should promote high activity.^{56,57}

ICP-OES spectroscopy

Table 2 shows the ICP-OES analysis results for the Ni@SnO₂ nanostructures, demonstrating that the experimental wt.%

Table 2 ICP-OES composition results for Ni@SnO₂ nanostructure powders

Sr. No.	Ni weight % value	
	Calculated	Observed
1	0.1% Ni@SnO ₂	0.102
2	0.2% Ni@SnO ₂	0.190
3	0.3% Ni@SnO ₂	0.294
4	0.4% Ni@SnO ₂	0.409
5	0.5% Ni@SnO ₂	0.492

loading of Ni was consistent with our theoretical calculations performed during the Ni loading studies.

Raman spectroscopy

Classically, rutile phase SnO₂ with a tetragonal structure gives rise to four basic Raman-active peaks centred at wavenumbers of 633, 755, 782 and 477 cm⁻¹, which are characteristically allocated to the A_{1g}, B_{1g}, B_{2g} and E_g modes respectively.^{58,59} These modes were significantly observed in the pristine and Ni@SnO₂ samples (Fig. 4 and Table 3). Moreover, a few Raman-silent modes, such the forbidden modes A_{2g} and B_{1u} as well as the infrared active modes Eu (TO), Eu (LO) and A_{2u}, were also observed (Fig. 4b).^{47,60,61}

The presence of IR-active modes in the Raman spectra could be associated with lattice imperfections and superficial

9	691.7 (A _{2u})	689
10	774.2 (B _{2g})	773

defects primarily due to the nanoscale size of SnO₂. However, the intensity of peaks associated with the Raman-active modes were observed to decrease, while the intensity increased

for the IR-active peaks, owing to various processes during electroless loading of Ni on the SnO₂ nanoparticle surface. Such processes may lead to the generation of a non-stoichiometric [110] plane reconstructed SnO_x surface. Additionally, peaks due to both the Raman and IR active modes were observed to be shifted to slightly lower frequencies, which could be attributed to the presence of surface vacancies.⁶²

UV-DRS spectroscopy

The bulk band gap (3.57 eV) of rutile-type SnO₂ is positioned at the C-point of its Brillouin zone, corresponding to the direct transition.²⁶ The optical properties of the Pristine-SnO₂ and Ni@SnO₂ nanostructures were evaluated using UV-DRS and Tauc plots (Fig. 5). The Pristine-SnO₂ sample exhibited a band gap of 3.72 eV, which is blue shifted relative to the bulk band gap owing to its nanosized nature, as seen from the FESEM and FETEM images. In the case of the Ni@SnO₂ nanostructures, the band gap values decreased slightly (bathochromic or red shift) upon increasing the Ni loading percentage from 0.1 to 0.5%, which may be attributable to the generation of defects and interaction between the d electrons of Ni²⁺ and the electrons obtained from O²⁻ and Sn⁴⁺.^{64,65}

Photoluminescence spectroscopy

The PL spectra of the pristine SnO₂ and Ni@SnO₂ nanostructures are shown in Fig. 6. At an excitation wavelength of 325 nm, all the samples exhibited two distinct broad emission bands, a higher intensity one around 364 nm (UV region) and another at 468 nm (visible region) having lower intensity. The presence of a peak at 364 nm (3.40 eV) could be attributed to the near-band-edge UV emission of the SnO₂ nanoparticles due to the radiative recombination of conduction band electrons and valence band holes. The visible region emission peak around 468 nm (2.65 eV) could be attributed to the non-radiative transition from defects such as interstitials and/or

Fig. 5 UV-DRS spectra (inset: Tauc plot) of pristine-SnO₂ and Ni@SnO₂ nanostructures.

Fig. 6 PL spectra of pristine SnO₂ and Ni@SnO₂ nanostructures.

vacancies forming inter-band trapped states.⁶⁶ When Ni was loaded on the SnO₂ nanoparticle surfaces, although similar PL signatures were observed for all the samples owing to the analogous lattice structure, an appreciable change in the intensity ratios of the peaks in the UV and visible regions could be noted.⁶⁶ The intensity of the peak around 364 nm gradually decreased with increasing the Ni loading from 0.1 to 0.5%, as penetration of light was hindered. Although a reduction in the intensity of the peak at around 468 nm was also observed, this reduction was most pronounced for 0.3% Ni@SnO₂ nanostructure sample. Thus, the Ni loading became a significant parameter as PL peak intensity suppressor *via* the generation of a non-radiative epicentre thwarting excessive e⁻/h⁺ pair recombination.⁴⁸ These effects aid not only in effective charge separation, but also in carrier mobility improvement.⁶⁷

FTIR spectroscopy

Fig. 7 presents the FTIR spectrum of pristine SnO₂ and the 0.1 to 0.5% Ni@SnO₂ nanostructures. FTIR analysis was carried out to examine the existence of functional groups and the vibrational stretching of chemical bonds. Usually, peaks below 1000 cm⁻¹ correlate with metal oxide bonds, and our samples exhibited analogous results.⁶⁸ A notable broad band in the 700–400 cm⁻¹ region is linked with the stretching modes of the vibrations of crossed-over bonds between Sn–O–Sn and Ni–Sn–O, indicating the formation of Ni-decorated SnO₂ nanostructures.^{69,70}

FESEM imaging

The surface morphologies of the prepared samples were examined using field emission scanning electron microscopy (FESEM) as shown in Fig. 8. The low-magnification images (Fig. 8a, c, e, g, i and k) corresponding to the as-synthesized SnO₂ and Ni@SnO₂ powders prepared with varying composition showed the formation of brick-like micron-sized agglom-

Fig. 7 FTIR spectrum of pristine SnO₂ and 0.1 to 0.5% Ni@SnO₂ nanostructures.

erated morphologies. The FESEM images of the as-synthesized SnO₂ and Ni@SnO₂ nanopowders at low magnification revealed spherical, rod-like, and irregular faceted nanoscale morphologies having sizes in the range of 30–60 nm (Fig. 8b, d, f, h, j, and l). In the Ni@SnO₂ nanopowders, the morphologies of the SnO₂ nanoparticles are not pronounced, which might be due to Ni nanoparticle loading/capping on their surfaces. However, Ni nanoparticles could not be distinctly observed in the FESEM images, probably due to their tiny size and capping.

FETEM imaging

FETEM images of 0.3%Ni@SnO₂ nanostructures are shown in Fig. 9. The low-magnification image divulged the formation of nanoparticles in the size range of 10–50 nm (Fig. 9a). The intermediate-magnification images presented in Fig. 9b and c revealed that the nanoparticles have spherical, irregular, hexagonal and faceted rod-like morphologies. Additionally, a few nanoparticles having sizes of 5–7 nm were also observed. The lattice images depicted in Fig. 9d and e reveal two important features of Ni loading. Ni was found to partially overlay the SnO₂ nanoparticle surfaces with a thickness of 1–2 nm and length of 50–60 nm (Fig. 9d). Additionally, the formation of Ni nanoparticles with a size of 5–7 nm over the SnO₂ nanoparticle surfaces was also observed (Fig. 9e). The coating/formation of Ni nanoparticles was confirmed by matching the lattice spacing values of these coating/nanoparticles with JCPDS *d*-values corresponding to the (111) and (200) planes of Ni.⁵²

High-resolution TEM images corresponding to 0.3% Ni@SnO₂ nanostructures (Fig. 9d and e) disclosed the significantly crystalline nature of the generated SnO₂ nanoparticles, most of them possessing a single-phase nature with different lattice orientations, as revealed from *d*-spacings of 3.26, 2.64 and 1.49 Å assigned to the (110), (101) and (310) planes,

Fig. 8 FESEM images of pristine SnO₂ (a and b) and 0.1 to 0.5% Ni@SnO₂ nanostructure powders corresponding to Ni loadings of (c and d) 0.1, (e and f) 0.2, (g and h) 0.3, (i and j) 0.4, and (k and l) 0.5% at low and high magnifications, respectively.

respectively. Thus, FESEM analysis supports the symbiotic manifestation of Ni on the SnO₂ surface.⁷¹

The corresponding SAED pattern (Fig. 9f) revealed the nanocrystalline nature of the 0.3%Ni@SnO₂ nanostructure, observed as regular spots in the rings. Further, intermittent diffraction rings in SAED pattern matching the (110), (101), (201), (211), (220) planes evince SnO₂ nanoparticles as the major contributor to the crystalline phase in the sample. The absence of nickel-related phases corroborated the XRD analysis. However, although high-resolution lattice imaging con-

firmed the presence of Ni nanoparticles, they could not be observed *via* either XRD or SAED due to their relatively small size and lower concentration.⁷²

EDS analysis equipped with elemental mapping was employed to evaluate the compositions of oxygen, tin and nickel, which matched approximately to the elements in 0.3% Ni@SnO₂ nanostructure as per the stoichiometry (Fig. 10a and b). Additionally, the elemental mapping images corresponding to these elements revealed that Ni was uniformly deposited over the SnO₂ surface (Fig. 10c, d and e).⁷²

BET surface area analysis

The results pertaining to BET surface area analysis of pristine SnO₂ as well as the Ni@SnO₂ nanostructures with respect to nitrogen adsorption and desorption isotherms, BJH pore size, *etc.*, are presented in Fig. 11 and Table 4. Nitrogen adsorption-desorption isotherms of type IV with H3 category hysteresis loops were observed for the as-synthesized pristine and nanostructure samples.⁷³ The surface area was calculated to be 9.9 m² g⁻¹ with a pore diameter of 1.8820 nm for the pristine SnO₂ sample. As the Ni loading was increased to 0.3%, the surface area was found to increase gradually to 19.6 m² g⁻¹ with a corresponding reduction in the pore diameter to 1.6769 nm, which might be due to the generation of tiny Ni nanoparticles as observed in the FESEM images. Further increasing the Ni loading led to a gradual decrease in the surface area due to excessive Ni nanoparticle loading, which filled the pores.⁷⁴

Photoelectrochemical study

Nyquist plot analysis furnishes a wide-ranging understanding of the interactions among charge transfer kinetics, recombination processes, and catalytic activity in defining the efficacy of hydrogen generation in photoelectrochemical systems. The typical plot is presented as a semicircle of a complex impedance plane, with superior potency indicated by a smaller semicircle at higher frequencies, which signifies fast charge transfer and a lower rate of recombination.⁷⁵

Pristine SnO₂ exhibited the largest semicircle, with an electrochemical reaction resistance (R_{ct}) of 130 Ω, while the lowest value of 65 Ω was observed for the 0.3%Ni@SnO₂ composite (Fig. 12). The distinctly superior electrochemical performance observed in the Nyquist plot for 0.3% Ni@SnO₂ compared with lower and higher Ni loading concentrations accentuates its potential as a propitious contender for photoelectrochemical hydrogen production applications (Fig. 12).

Faster charge transfer kinetics at the electrode-electrolyte interface were demonstrated *via* the smaller semicircle in the Nyquist plot for 0.3% Ni@SnO₂, which enables efficient conversion of photoexcited electrons to hydrogen ions, leading to higher hydrogen evolution rates. At lower Ni@SnO₂ composite surface deposition concentrations, the insufficient loading levels lead to slower charge transfer kinetics, whereas at higher loading concentrations of Ni, increased surface deposition

causes reorganization or electronic effects that hinder charge transfer; the optimum balance of both is achieved at 0.3% Ni loading.

Photoconductivity study

The I - V characteristics of pristine SnO₂ and 0.3% Ni@SnO₂ photodetectors with a voltage sweep of -10.0 V to 10.0 V are shown in Fig. 13a. The linear behaviour of all the I - V curves confirmed the generation of ohmic contact between the samples and the ITO electrodes. The observed photocurrents for the pristine SnO₂ and 0.3% Ni@SnO₂ photodetectors under the light illumination were 16.5 nA and 20.9 nA, respectively, compared to 10.91 nA for the same measurement in the dark for 0.3% Ni@SnO₂ photodetectors. The nickel loading on the SnO₂ surface effectively improved the charge transport, leading to an enhancement of the photocurrent. The photo-response of the pristine SnO₂ and 0.3% Ni@SnO₂ based photodetectors at 0.5 V bias voltage is shown in Fig. 13(b) for five cycles. Both the pristine SnO₂ and 0.3% Ni@SnO₂ sample based photodetectors showed a swift response to light with a constant and stable current over several cycles. The rise times observed for the pristine SnO₂ and 0.3% Ni@SnO₂ photodetectors under light illumination and dark conditions were found to be 800 , 600 and 1200 ms, with corresponding fall times of 1210 , 1000 and 1800 ms, respectively. The presence of nanoscale Ni loading on the SnO₂ surfaces improves charge separation and introduces additional electrochemical reaction

Fig. 13 (a) I - V characteristics and (b) photo-response of pristine SnO₂ and 0.3% Ni@SnO₂ photodetectors.

pathways or active sites, leading to an increase in the overall photocurrent response.

Cyclic voltammetry (CV) profiles of SnO₂ and 0.3% Ni@SnO₂ were obtained (Fig. 14) to further probe their photoelectrochemical behaviour. Although the CV profiles did not exhibit the rectangular shape typically associated with ideal capacitive behaviour, the increase in current observed for the 0.3%Ni@SnO₂ as compared to pristine SnO₂ indicated an enhancement in photoelectrochemical activity. The higher current in the 0.3%Ni@SnO₂ revealed the generation of a greater number of charge carriers and/or a more efficient charge transfer process, which could be directly correlated with an increase in charge storage capacity. Additionally, the larger area enclosed in the CV curves of 0.3%Ni@SnO₂ signified higher capacitance, reflecting the material's ability to store and discharge more charge carriers.

Photocatalytic water splitting

Photocatalytic hydrogen generation trials were carried out by employing the Ni@SnO₂ nanostructures under visible light irradiation in the water splitting reaction facilitated by a 20% aqueous methanol (v/v) solution, and the noteworthy conclusions are presented in Fig. 15. During the hydrogen evolution process, methanol plays dual roles, primarily as a sacrificial reagent to efficiently subdue the oxygen evolution rate, and secondly, participating in an irrevocable reaction with the photogenerated valence band holes from the semiconductor to reduce the rate of charge carrier recombination, which, in turn, assists in the amplification of photocatalytic activity.⁷⁶ For the pristine SnO₂ sample, a maximum hydrogen production of 24 μmol g⁻¹ (in 3 h) was found, which was the smallest among all the samples (Fig. 15). The hydrogen production rate of Ni@SnO₂ nanostructures at lower Ni loading concentrations were substantially small but exhibited a noteworthy increase with higher loading until the 0.3%Ni@SnO₂ nanostructure sample. Above 0.3% Ni loading, a steady decline in

Fig. 14 C–V measurement of pristine SnO₂ and 0.3% Ni@SnO₂ samples.

Fig. 15 Photocatalytic hydrogen generation rates of the prepared pristine SnO₂ and Ni@SnO₂ nanostructures.

the hydrogen production was noted. The hydrogen generation data for all samples are summarized in Table 1, and the highest hydrogen evolution rate was detected for the 0.3% Ni@SnO₂ nanostructure with a value of 49.9 μmol h⁻¹ g⁻¹, which is ~6 times higher than that for the pristine SnO₂ sample. The achieved photocatalytic water splitting value for the 0.3%Ni@SnO₂ nanostructure was found to be on par with reported values, as presented in Table 5. It may be noted that most of the reports presented in Table 5 deal with the doping of SnO₂ with different materials. However, doping may not be an efficient process, due to the non-uniform distribution of dopants. Additionally, there are a few reports on the use of noble metals such as platinum on the SnO₂ surface, which makes the process uneconomical.

This increase in the photocatalytic performance can be attributed to the loading with Ni, an efficient noble metal (Pt)-free co-catalyst, effecting swift and effortless charge separation for surface-activated SnO₂ semiconductor nanoparticle bands. It may be noted that Ni not only acts as a co-catalyst, but also interacts electronically, as inferred from Raman, UV-visible

Table 5 Comparison of photocatalytic performance of Ni@SnO₂ nanostructures with reported SnO₂ composites

Sr. No.	SnO ₂ -based Material	H ₂ generation yield μmol g ⁻¹ h ⁻¹	Ref.

and PL spectroscopic data, probably creating directional charge transfer channels.⁷⁷ The strong electronic interface between Ni-related surface states (playing a role similar to a dopant) and the SnO₂ matrix material states through these channels affects the surface acceptor states, with ensuing negative charge at the semiconductor surface.⁵¹

The photocatalytic water splitting mechanism comprises sunlight absorption by semiconductor photocatalysts (SnO₂) transferring electrons from the valence band (VB) to the conduction band (CB), leaving behind holes in the VB. These holes produce protons (H⁺) and radicals *via* the oxidization of methanol.⁷⁸ Simultaneously, generation of molecular hydrogen by the reduction of protons through the electrons of the CB occurs by means of a sequence of reactions.⁷⁹ However, this process occurs if rapid recombination of electrons and holes is retarded. In case of the pristine SnO₂ sample, the observed low H₂ production is attributable to the rapid recombination of such photogenerated charges. In the case of the Ni@SnO₂ nanostructures, the significant enhancement in the hydrogen evolution with varying nickel loading concentrations in SnO₂ can be ascribed to several aspects. Initially, the increase in nickel loading from 0.1% to 0.3% enhanced the density of active sites available on the surface of the SnO₂ nanoparticles, which facilitated effective hydrogen evolution reaction (HER). Additionally, nickel acts as a co-catalyst for the HER due to its ability to adsorb hydrogen atoms and enable their combination to form hydrogen molecules, eliminating the need for the expensive Pt co-catalyst. At lower Ni loading concentrations, the presence of nickel enhances the catalytic activity of the SnO₂ surface, promoting the HER. However, beyond 0.3% Ni loading, excessive nickel may result in the formation of inactive nickel clusters causing catalytic poisoning, leading to a decline in the catalytic activity and consequently, in the hydrogen evolution rate.

Noble metals such as Au, Ag, Pt, *etc.*, have been reported to alter the electron distribution to improve SnO₂-based photocatalytic H₂ production.²⁴ The conduction band level of the target matrix SnO₂ (−0.42 eV), is higher than that of Ni (−0.23 eV) above the H₂ evolution potentials, forming a Schottky barrier at the contact interface. Electrons drift from the high energy levels of SnO₂ to Ni, which acts as an electron acceptor, confining the electrons, which in turn averts photogenerated charge carrier recombination.^{80,81} Consequently, the efficiency of photocatalytic H₂ production by autocatalytically deposited Ni on the SnO₂ photocatalyst surface was found to be greatly enhanced.²⁴

It is worth noting that the obtained photocatalytic hydrogen production data was substantiated by the PL spectroscopy and BET results. In the PL results, the intensity of peaks corresponding to near-band-edge UV emission (364 nm) and defects (468 nm) were quenched due to generation of a non-radiative epicentre (Fig. 6). Additionally, the BET surface area increased until the Ni loading reached 0.3% and then decreased for the Ni@SnO₂ nanostructures. Both these effects eventually affected the photocatalytic hydrogen production. CV data provided substantial evidence that Ni loading enhanced the

charge capacitance of SnO₂, indicating better electrochemical performance. However, further optimization is needed to achieve efficient solar hydrogen production.

Conclusion

A hitherto unreported Ni@SnO₂ photocatalytic system active under visible light was prepared by the co-precipitation synthesis of SnO₂ nanoparticles followed by autocatalytic Ni loading. The nickel loading was varied from 0.1 to 0.5 wt% on surface-activated SnO₂ nanopowders. Ni was uniformly deposited as nanoparticles and surface coating onto the SnO₂ nanopowder surface, as confirmed by FETEM equipped with EDS as well as XPS spectroscopy. The Ni²⁺ loading on the SnO₂ nanopowder surface quenched the PL peak intensity and modified the defect band structure, leading to efficient photogenerated charge carrier separation. The significant improvement in photocatalytic H₂ production for the Ni@SnO₂ nanostructures compared to the pristine SnO₂ nanoparticles could be ascribable to Schottky barrier formation between SnO₂ to Ni and subsequent transfer of photogenerated electrons from the semiconductor to the metal. A maximum hydrogen generation of ~50 μmol g^{−1} h^{−1} was recorded for the 0.3%Ni@SnO₂ nanopowder, which was almost ~6 greater more than the 8.52 μmol g^{−1} h^{−1} obtained for the pristine SnO₂ nanopowder. The present work highlights the efficacy of the autocatalytic deposition technique in producing a hitherto unreported effective and economical Ni@SnO₂-nanostructure-based heterogeneous photocatalyst. We optimistically believe that the autocatalytic deposition technique elaborated in the present study will represent an innovative pathway for surface decoration of exceedingly competent heterogeneous photocatalytic systems for semiconductor materials.

Author contributions

The experiments have been planned & performed by P. N. B. under the supervision of B. K., who introduced the idea of electroless Ni plating. S. R., R. C. and S. G. have supported the characterization. The data were analysed by P. N. B., M. S. and S. A. All the authors have participated in writing the manuscript.

Data availability

Data will be made available on request.

Conflicts of interest

There are no conflicts to declare.
