## Solving ZIB challenges: the dynamic role of water in deep eutectic solvents electrolyte†

E. Emanuele,<sup>id</sup>\*<sup>a</sup> G. Batignani,<sup>b</sup> G. Cerullo,<sup>c</sup> G. Leita,<sup>a</sup> N. Madathiparambil Mohanan,<sup>b</sup> E. Mai,<sup>id</sup><sup>bd</sup> M. Martinati,<sup>b</sup> C. Mele,<sup>e</sup> T. Scopigno<sup>b</sup> and B. Bozzini<sup>a</sup>

Zinc-ion batteries (ZIBs) emerge as a promising technology in the post-lithium-ion era, offering high theoretical energy density, lower manufacturing costs, and enhanced safety. Zn<sup>2+</sup> solvation plays a crucial role in the performance and durability of ZIBs, that warrant research since they are still far from industrial standards. As far as Zn<sup>2+</sup> solvation is concerned, in aqueous electrolytes, two types of water molecules are found: free water molecules and solvated water molecules that participate in Zn<sup>2+</sup> solvation structure [Zn(H<sub>2</sub>O)<sub>6</sub>]<sup>2+</sup>. The free water easily reacts with metallic Zn at the electrode/electrolyte interface, leading to a range of parasitic processes that critically impact durability: hydrogen evolution, passivation, and anode shape changes. Alternative electrolytes such as Deep Eutectic Solvents (DESs) can be used to modulate the Zn solvation shell and limit free water molecules, while still preserving the green and safe characteristics of aqueous-based ones. The electrolyte–electrode interface and zinc solvation structure are effectively tuned by adjusting the hydration percentage of DES, leading to improved Zn plating and stripping processes. This study investigates the electrochemical behavior of zinc in ethaline DES with varying water contents, transitioning from water-in-salt to salt-in-water structures. Electrokinetic and electro-crystallization analyses were performed using cyclic voltammetry and chronoamperometry, complemented by galvanostatic cycling tests of Zn|Zn symmetric cells while ions speciation and DES transitions were followed by Spontaneous Raman, Stimulated Raman Scattering (SRS) and Impulsive Stimulated Raman Scattering (ISRS) spectroscopies. Moreover, *in situ* Surface-Enhanced Raman spectroscopy (SERS) was used to follow the interface changes and organic component degradation. The results highlight the impact of hydration on the electrochemical stability and zinc deposition mechanisms, providing crucial insights for optimizing ZIB anode performance.

### 1. Introduction

Lithium-ion batteries (LIBs) dominate the energy storage market due to their high energy density, long cycle life, lightweight design, and rapid charging capabilities.<sup>1</sup> However, growing concerns regarding safety and the limited availability of lithium resources have driven the exploration of alternative energy storage systems.<sup>2</sup> ZIBs have emerged as a promising alternative, offering substantial technological potential. These advantages include high theoretical energy density, cost-effective manufacturing, abundant raw materials, and

enhanced safety features.<sup>3–5</sup> ZIBs typically operate with neutral or weakly acidic aqueous electrolytes, but face several challenges, such as hydrogen evolution, passivation, and shape changes at the Zn anode.<sup>6,7</sup>

In aqueous electrolytes, water molecules exist in two forms: free water molecules and solvated water molecules that participate in the Zn<sup>2+</sup> solvation structure, [Zn(H<sub>2</sub>O)<sub>6</sub>]<sup>2+</sup>. The solvation effect weakens the O–H bond, accelerating water decomposition during zinc deposition, while free water easily reacts with metallic Zn at the electrode|electrolyte interface, leading to the aforementioned irreversible processes.<sup>8,9</sup>

Reducing the number of free water molecules in the electrolyte is thus critical for minimizing side reactions and improving Zn plating/stripping reversibility. DESs offer a potential alternative to aqueous electrolytes, allowing modulation of the Zn solvation shell while retaining the environmentally friendly and safe properties of water-based systems. DESs are mixtures of two components: a hydrogen bond donor (*e.g.*, amides, carboxylic acids, or polyols) and a hydrogen bond acceptor (*e.g.*, quaternary ammonium salts), forming a eutectic mixture with a melting point lower than that of the individual

components.<sup>10</sup> DESs share similar properties with ionic liquids (ILs), such as good thermal stability, low vapor pressure, and high electrochemical stability, but with advantages such as lower cost, non-toxicity, and biodegradability.<sup>11–14</sup>

Although DESs have many advantageous properties for battery applications, their sluggish kinetics, high viscosity and low ionic diffusivity pose significant challenges for electrochemical applications.<sup>15</sup> To address these drawbacks, water can be added as a cosolvent to reduce viscosity and increase the diffusion coefficient of electroactive species without disrupting the eutectic structure, up to a hydration limit of 40–50 vol%.<sup>16</sup> The addition of water to DES can modify both the electrolyte–electrode interface (tuning the thickness) and the Zn<sup>2+</sup> solvation structure. It is thus crucial to develop a grasp over the tuning capabilities of the solution chemistry and of the electrode–electrolyte interfacial structure and chemistry. In principle, the combined use of DES and water provides a flexible tool to achieve this goal.

Ibrahimi *et al.* demonstrated that the addition of a cosolvent to a ChCl/Urea DES solution significantly alters zinc deposition kinetics, affecting the nucleation process and shifting from a 2D nucleation mechanism in pure DES to a 3D progressive nucleation mechanism with the cosolvent.<sup>17,18</sup> Water acts as an effective cosolvent, reducing viscosity and enhancing conductivity, forming a “water-in-eutectic” structure. However, beyond a certain hydration level, the system transitions from a “water-in-eutectic” structure to a typical aqueous solution, making careful hydration control crucial.<sup>19</sup>

Batteries cycled with controlled hydration levels demonstrate better cycling performance compared to anhydrous systems.<sup>20–24</sup> For example, Yang *et al.* reported that a hydrated DES (Zn(CLO<sub>4</sub>)<sub>2</sub>·6H<sub>2</sub>O/SN) achieved dendrite-free Zn plating/stripping with a 98% cathodic efficiency and stable polarization voltage.<sup>22</sup> Similarly, Han *et al.* demonstrated that Zn(CLO<sub>4</sub>)<sub>2</sub>·6H<sub>2</sub>O/MSM electrolytes enabled stable Zn plating/stripping for over 2000 hours at 0.05 mA cm<sup>-2</sup>, with stable voltage even at high current densities (2 mA cm<sup>-2</sup>).<sup>20</sup> In other studies, cells with Zn(TFSI)<sub>2</sub>-sulfonane-H<sub>2</sub>O electrolytes cycled stably for over 8800 hours at 0.5 mA cm<sup>-2</sup> and over 9600 hours at 1 mA cm<sup>-2</sup>,<sup>21</sup> and cells using Zn<sup>2+</sup>/EG/H<sub>2</sub>O maintained stable performance for 4500 hours at higher current densities.<sup>23</sup>

Despite these promising results, the role of water in DES remains unclear, with claims suggesting that no “free” water exists in these systems. Instead, water molecules are believed to interact directly with DES components in a “confined” state within the eutectic framework.<sup>24</sup> Water increases conductivity, ion diffusivity, and dissociation, leading to a lower activation energy and improved reaction kinetics. A finely tuned water-deficient solvation structure has been shown to enable high ion dissociation while suppressing detrimental water activity.<sup>23</sup> For example, Shi *et al.* demonstrated that zinc electrodeposition involves successive desolvation reactions, with the aquo complex desolvation energy being lower than that of other species.<sup>25</sup> Abbott *et al.* further studied Zn coordination in ChCl/U and ChCl/EG DESs, showing that when ZnSO<sub>4</sub> is dissolved in anhydrous ethaline, [ZnCl<sub>4</sub>]<sup>2-</sup> is formed and stabilized by choline.<sup>16,26</sup> Our previous work<sup>27</sup> revealed unusual voltammetric

behavior due to Zn<sup>2+</sup> coordination in DESs, characterized by a cathodic peak corresponding to Zn deposition from an intermediate Zn species (Z), formed through the reduction or deprotonation of choline chloride (ChCl) and/or ethylene glycol (EG). In ref. 27, we investigated the effect of different cathodic materials on the kinetics of Zn electrodeposition. However, a mechanistic understanding of the effect of water on the eutectic network and Zn solvation, as it relates to electrochemical performance, was completely lacking.

While several studies have reported improved cycling stability in hydrated DES systems, to the best of our knowledge, the unusual voltammetric behavior and potential-time transients observed in hydrated DES electrolytes have not been extensively explored.

In this study, we investigate the electrochemistry of Zn in ethaline (DESEG) with varying water contents (0 wt%, 1 wt%, 3 wt%, 10 wt%, 20 wt%, and 50 wt%), transitioning from a “water-in-salt” structure to a “salt-in-water” structure. Our goal is to understand the role of water in Zn coordination, the eutectic structure, and the formation of the Z intermediate. Electrokinetic and electro-crystallization studies were conducted using cyclic voltammetry (CV) and chronoamperometry (CA), complemented by galvanostatic cycling tests in Zn|Zn symmetric CR2032 coin cells. Additionally, the Zn solvation structure was investigated using a combination of vibrational spectroscopies, including Spontaneous Raman, Stimulated Raman Scattering (SRS), and Impulsive Stimulated Raman Scattering (ISRS). Interfacial changes and decomposition of the electrolyte were followed by *in situ* Surface-Enhanced Raman Spectroscopy (SERS). This multi-technique approach provides valuable insights into the Zn plating reaction and offers a framework for optimizing DES hydration, reducing free water content, and mitigating the main drawbacks associated with eutectic electrolytes.

## 2. Materials and methods

### 2.1. Synthesis of deep eutectic solvents

**2.1.1. Synthesis of anhydrous ethaline.** A pre-drying process was performed to eliminate the crystallization water of choline chloride, and ZnSO<sub>4</sub> (reagent plus, ≥99% Sigma-Aldrich) powders by heating these powders separately at 120 °C under a rotary-pump vacuum for 2 days. After drying, the chemicals were transferred to an argon-filled glove box for the preparation of anhydrous ethaline, which was then used for the preparation of DES EG. Ethaline was first prepared by combining ethylene glycol (C<sub>2</sub>H<sub>6</sub>O<sub>2</sub>) (reagent plus, ≥99% Sigma-Aldrich) and choline chloride (C<sub>5</sub>H<sub>14</sub>ClNO, Sigma-Aldrich 99%) (2 : 1 molar ratio) at a temperature of 70 °C for 1 h until a homogeneous colorless solution was obtained. Then, ZnSO<sub>4</sub> was added to ethaline to obtain a 0.3 M solution used as electrolyte for coin cell cycling.

**2.1.2. Synthesis of hydrated ethaline.** To regulate the electrolyte's hydration percentage, a precise quantity of water was introduced after the synthesis of anhydrous ethaline, prepared as described in Section 2.1.1. As indicated in the introduction, the liquid structure of the DES remains intact in

the presence of water up to 50 vol%. Consequently, six distinct hydration levels were chosen to test the liquid structure behavior in different liquid structure conditions ranging from 0%–50% in electrochemical tests and 0–99% for Raman spectroscopy studies. To create DES with varying hydration levels, a 0.3 M water solution of ZnSO<sub>4</sub> (reagent plus, ≥99% Sigma-Aldrich) was added, ensuring a constant concentration of Zn<sup>2+</sup> species.

## 2.2. Coin cell fabrication

Cycling tests were carried out in symmetric CR2032 coin cells. The electrodes were Zn disks 12 mm in diameter, punched from 250 μm thick foil. The separator consisted of glass microfiber disks 19 mm in diameter and 260 μm thick. An amount of 120 μL of electrolyte, prepared as described in Section 2.1.1 and 2.1.2, was added to the cell.

## 2.3. Electrochemical measurements

**2.3.1. Cyclic voltammetry (CV).** CV measurements were performed in a three-electrode cell with an Ag/AgCl 3 M KCl reference electrode (RE)(AMEL 373/SSG/12, Milano, Italy) and platinum counter electrode (CE). All potentials in this work are referenced to the Ag/AgCl 3 M KCl electrode unless otherwise stated. A Zn rod with a surface area of 79.94 mm<sup>2</sup> was employed as working electrode (WE). The cell contained 40 mL of electrolyte (see Section 2.1 for the composition), which was degassed by Ar bubbling (0.5 nlt min<sup>-1</sup>, 30 min) before running the experiment and kept under a blanket of flowing Ar during the electrochemical measurements. CVs were performed with a VMP-300 BioLogic potentiostat/galvanostat at 10 mV s<sup>-1</sup>. Specifically, before each experiment, the electrode was washed with 50% HNO<sub>3</sub>, gently polished with alumina suspension 0.05 μm (ALLIED, Hanover, MD, USA) and finally rinsed with DI water and acetone. The RE and all cell components were thoroughly washed with DI water.

**2.3.2. Rotating disk electrode (RDE).** The role of intermediate products and activity of side reactions were evaluated using a rotating disk electrode (RDE) setup (Pine Research Instrumentation, based on an MSR Rotator), driven with rotational speed controller (Model AFMSRCE, Pine Instrument Co.) coupled with a potentiostat (VMP-300, Biologic Science Instruments). A typical three electrode system was employed, including a glassy carbon electrode (GC, Diameter 5 mm, Pine research Instrumentation) as the working electrode, a platinum wire (AMEL), as the counter electrode, and Ag/AgCl 3 M KCl reference electrode (AMEL 373/SSG/12, Milano, Italy). The working electrode was polished before each measurement with 0.3 μm alumina on microcloth, washed with acetone and then dried. The Pt ring was cleaned with acetone on a cotton paper.

**2.3.3. Chronopotentiometry (CP).** CP experiments were conducted using the same set-up mentioned in Section 2.3.1, using a Zn foil with an area of 0.382 cm<sup>2</sup> as the working electrode. A 0.3 M ZnSO<sub>4</sub> solution in DES ChEG was used at 30 °C imposing a current of -0.191 mA to obtain a current density 0.5 mAcm<sup>-2</sup> for a total of 30 min.

**2.3.4. Galvanostatic-charge-discharge cycles (GCD).** GCD measurements were carried out with a NEWARE Battery Testing System (model: CT-4008T-5V10mA-164). The Zn|Zn symmetric cells were cycled at 0.5 mA cm<sup>-2</sup> for 30 min at each current density (CD), and the voltage was limited by setting the cut-off to ±4 V. Cell assembly is reported in Fig. S1.†

## 2.4. Electrolyte characterization

**2.4.1. Raman spectroscopy.** Raman spectra of the electrolyte were measured with a Renishaw InVia micro-Raman spectrometer, equipped with diode-pumped solid-state lasers emitting at 532 nm or 660 nm excitation wavelengths. The laser was focused on the sample using a 50× objective and the laser power on the sample was varied in the ranges: 0.07–70 mW (for 532 nm) and 0.0754–75.4 mW (for 660 nm).

**2.4.2. SRS and ISRS.** SRS spectra are generated by the joint action of a narrowband Raman pump (RP) and a broadband probe pulse (PP).<sup>28</sup> When the frequency difference between the RP and PP spectral components matches a vibrational mode, the Raman signal is coherently stimulated and emitted in the probe direction. Both the Raman and probe pulses for the SRS experiment are generated from a Ti:sapphire laser source, which outputs 40 fs transform-limited pulses centered at 800 nm, with an energy of 2.5 mJ at 1 kHz repetition rate. The RP is synthesized using a commercial two-stage optical parametric amplifier (Light Conversion TOPAS-C),<sup>29</sup> which outputs tunable IR-visible pulses. These pulses are subsequently frequency-doubled at 630 nm and spectrally compressed *via* second harmonic and sum frequency generation<sup>30</sup> in a 25 mm-thick beta barium borate crystal. Then the Raman pulse is spectrally narrowed using a (4f) spectral filter, simultaneously rectifying its temporal profile.<sup>31</sup> The energy of the RP is adjusted using a variable attenuator, delivering 1 μJ pulses onto the sample. To produce the PP, a small fraction of the laser is focused onto a 3 mm sapphire crystal, generating a broadband white light continuum. The pulses are finally focused onto the sample in a non-collinear geometry (~5°), and the PP spectrum is recorded using a charge-coupled device (CCD) detector after being dispersed by a spectrometer, collecting the blue side SRS response, or stimulated Raman loss.<sup>32</sup> To record consecutive probe spectra in the presence and absence of the RP, a synchronized chopper blocks the RP at 500 Hz. Additional details on the SRS setup can be found in ref. 33.

The pump and the probe pulses used for the broadband ISRS experiment<sup>34–37</sup> are synthesized from a Yb laser, which generates 1030 nm pulses at a 20 kHz repetition rate and with an energy of 0.5 mJ. The pump is obtained by a home-made non-collinear optical parametric amplifier,<sup>29</sup> which generates ultra-broadband (700–1000 nm) pulses,<sup>38</sup> compressed down to 10 fs by a pair of chirped mirrors.<sup>39</sup> The fluence is controlled by a variable attenuator and the energy acting on the sample is maintained below 800 nJ per pulse. The broadband probe pulse is synthesized using the same method as in the SRS experiments, by focusing a small fraction (approximately 1 μJ) of the laser beam onto a 3 mm sapphire crystal, obtaining

a broadband white light continuum. The pump and the probe pulses are then focused onto the sample in a non-collinear geometry ( $\sim 5^\circ$ ).

#### 2.4.3. *In situ* surface enhanced Raman spectroscopy.

Raman spectra were recorded by means of a Jobin Yvon Horiba LabRam microprobe confocal system with the excitation at 633 nm provided by a He–Ne laser delivering 7 mW at the sample surface, with a 600 grid per mm spectrometer. A  $50\times$  long-working distance objective was used. *In situ* electrochemical measurements were performed in a Ventacon glass cell. The working electrode was a gold disc electrode, 0.6 mm in diameter, embedded in a Teflon holder; the counter electrode was a platinum wire loop concentric and coplanar with the working electrode, and the reference was an aqueous Ag/AgCl 3 M KCl electrode. In order to achieve SERS activity, the gold electrode was submitted to Oxidation-Reduction Cycling (ORC) treatment which consisted of cycling the electrode in a separated cell in 0.1 M KCl solution, from 0.3 to 1.2 V at  $500\text{ mV s}^{-1}$  fifty times: a typical ORC cycle is shown in Fig. 6. *In situ* Raman spectra were collected during potentiostatic polarization of the gold electrode at a series of potentials covering the span investigated by voltammetry.

### 3. Results and discussion

The electrokinetic and electrode reaction processes governing Zn electrodeposition in ethaline, with varying degrees of hydration, were investigated using CV on both stationary and rotating disk electrodes, as well as CA measurements.

Initially, stationary CV was performed using ethaline without  $\text{ZnSO}_4$  at  $30^\circ\text{C}$ , under different hydration levels (Fig. 1, panel B). The scan started cathodically from  $-1.25\text{ V vs. Ag/AgCl}$  (to prevent Zn electrode corrosion) and extended to  $-1.8\text{ V}$ , at a scan rate of  $10\text{ mV s}^{-1}$ .

The cathodic potential limits reported for anhydrous DES EG are attributed to the reduction of choline ions ( $\text{Ch}^+$ ) or ethylene glycol. As described in our previous work,<sup>27</sup> quaternary ammonium salts can undergo electrochemical decomposition, leading to the formation of trimethylamine and ethanol radicals or dimethylaminoethanol and methyl radicals. Furthermore, the trimethylamine formed can be deprotonated by either  $\text{OH}^-$  or  $\text{H}^+$ , forming HCN.

When water is added to the anhydrous eutectic electrolyte, an increase in current density is observed along with a slight decrease in the electrochemical stability window (ESW). The widening of the ESW can be achieved due to the suppression of water splitting in low-hydration electrolytes. In contrast, water clusters and free-water molecules in highly hydrated eutectic electrolytes promote the transfer of protons/hydroxides, thus favoring the hydrogen evolution reaction (HER).

When water is added into the hydrogen bond network of the eutectic system, intrinsic  $\text{H}_2\text{O-H}_2\text{O}$  hydrogen bonds break, forming clusters of choline- $\text{H}_2\text{O}$  and chloride- $\text{H}_2\text{O}$  hydrogen bonds. Consequently, water hydrates the pure DES by sequestering around the cholinium cation and chloride anion, although the DES structure remains intact up to a water content of approximately 40–50%.<sup>40</sup> The observed mechanisms can be

summarized as shown in Fig. 1A. The newly formed clusters limit the diffusion and separation of proton/hydroxide ion products, inhibiting water activity. Additionally, the stronger O–H bond in  $\text{H}_2\text{O}$ , due to the formation of choline- $\text{H}_2\text{O}$  and Cl- $\text{H}_2\text{O}$  bonds (disappearance of the Raman stretching band at  $3628\text{ cm}^{-1}$ ), further increases the difficulty of water splitting.

The hydrated electrolytes show a higher current density compared to the anhydrous one, primarily due to differences in viscosity. The high viscosity of anhydrous DES arises from the hydrogen bonds and van der Waals interactions that limit ion and molecular mobility, increasing resistance to fluid flow.<sup>41</sup> Hydration, on the other hand, reduces viscosity by decreasing the number of HBA–HBD hydrogen bonds per molecule as water content increases, facilitating ion mobility.<sup>42</sup>

Cyclic voltammograms of ethaline with 0.3 M  $\text{ZnSO}_4$  are shown in Fig. 1 (panel C). This study focuses on the Zn deposition process and, therefore, the cathodic electrode reactions. The voltammetric response varies depending on the water content in the electrolyte. Arrows and numbers are added to track the CVs behavior during the scan.

When  $\text{ZnSO}_4$  is dissolved in anhydrous ethaline, the  $[\text{ZnCl}_4]^{2-}$  species is formed and stabilized by choline. The specific coordination of  $\text{Zn}^{2+}$  results in unique voltammetric behavior, characterized by backward cathodic peak in the cathodic branch.<sup>27</sup>

Although tetrachlorozincate is the dominant species, it does not appear to be the complex from which Zn is deposited, as  $[\text{ZnCl}_4]^{2-}$  has a highly negative reduction potential. Mechanistic studies of Zn electrodeposition onto various cathodic materials suggest that the metal is formed *via* the reduction of an intermediate Zn-containing species (Z). The organic components of the eutectic solvents can be dehydrogenated at negative potentials, forming  $\text{RO}^-$ , which can replace one or more chloride ligands in  $[\text{ZnCl}_4]^{2-}$ . As a result, the intermediate species Z is formed, and the corresponding peak appears only in the backward scan, after the potential has reached the voltage required for the formation of  $\text{RO}^-$ .<sup>27</sup>

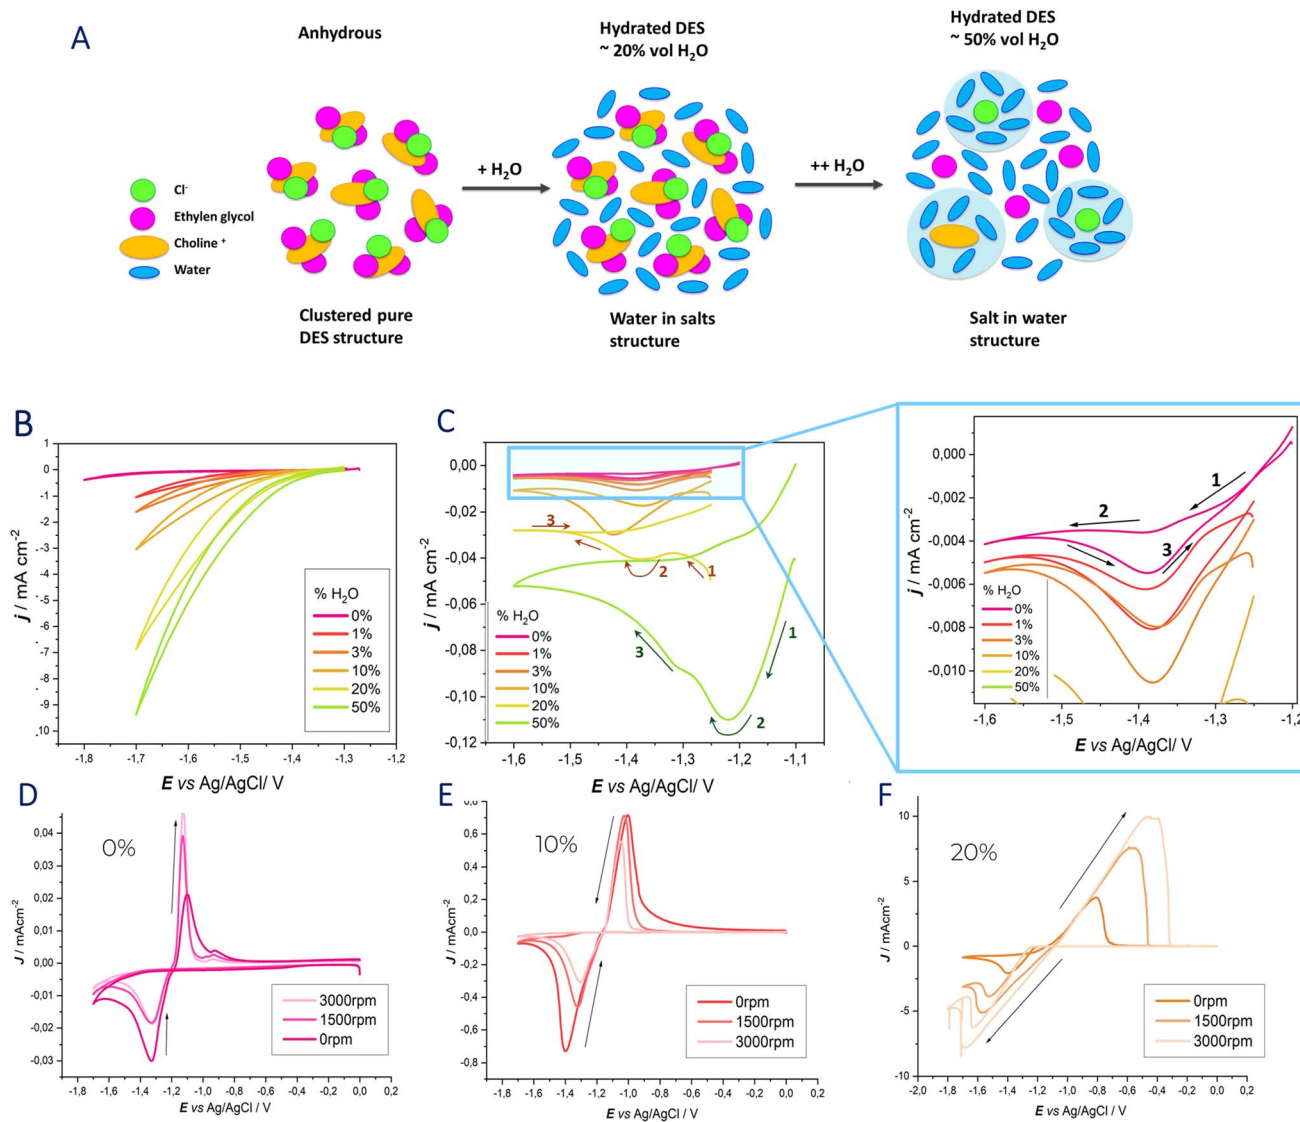

Previous *in situ* SERS studies of the DES-EG|Au interface revealed that at potentials lower than  $-1.5\text{ V vs. Ag/AgCl}$ ,  $\text{CN}^-$  groups were adsorbed onto the electrode surface and desorbed at positive potentials.

Therefore, at potentials below  $-1.5\text{ V vs. Ag/AgCl}$ , two concurrent effects occur: the reduction of the electrolyte and the blocking of the electrode surface. When the surface is blocked, potentially by degradation products of the DES or adsorbed hydrogen, depending on the hydration, as evidenced by the appearance of a new peak at  $2045\text{ cm}^{-1}$  in the DESEG|Au interface SERS data (reported below), the concentration of Z in the diffusion layer increases.

As the scan moves toward more positive potential, the blocking layer desorbs, allowing zinc deposition from Z, as shown by a reduction peak in the backward scan.

When water is added, a low current density forward peak becomes visible, and this behaviour remains consistent up to a water content of 10% wt. Notably, the peak current is always highest during the reverse scan.

**Fig. 1** (A) schematic representation of solvation regimes presents in eutectic solvents, the transition of the eutectic/ $\text{H}_2\text{O}$  systems from a “water-in-eutectic” to an ordinary “aqueous solution” regime. (B) Cyclic voltammograms performed at  $10 \text{ mV s}^{-1}$  on stationary Zn electrode of pure ethaline DES with different percentage of water content. (C) Cyclic voltammograms performed at  $10 \text{ mV s}^{-1}$  on stationary Zn electrode of  $0.3 \text{ M ZnSO}_4$  DESEG with different water contents. (D–F) Cyclic voltammograms performed at  $10 \text{ mV s}^{-1}$  on RDE electrode of  $0.3 \text{ M ZnSO}_4$  DESEG with 0%, 10% and 20% water fractions, respectively.

At 20% wt, the voltammograms show a cathodic peak on the initial cathodic sweep, unlike those recorded with less hydrated DES. This phenomenon is likely due two concurrent effect: a reduced ESW and a less blocked electrode surface. As stated above, the narrow ESW found with higher hydration is due to water decomposition. Water molecules hydrogen-bonded to DES components can be reduced at cathodic potentials, forming  $\text{H}^\bullet$  radicals, which may participate in the decomposition of organic components. This side reaction can generate  $\text{RO}^-$  ligands at less negative cathodic potentials that contribute to the formation of the Z intermediate increasing the number of reactants that undergo reduction already in the forward scan. Moreover, SERS measurements revealed that at 20% wt, only the peak related to Au–H stretching is present.

At 50% wt the voltammograms show a cathodic peak on the ongoing scan with an increased current density. As hydration increases in the eutectic system,  $\text{Zn}^{2+}$  coordination changed, forming  $[\text{ZnCl}_3(\text{H}_2\text{O})]^-$  (this will be discuss better on the basis of Raman measurements). The water molecule in the  $\text{Zn}^{2+}$  coordination sphere has a lower energy barrier than chloride for stepwise desolvation, meaning  $[\text{ZnCl}_3(\text{H}_2\text{O})]^-$  has a lower dissociation energy than  $[\text{ZnCl}_4]^{2-}$ , resulting in faster desolvation and reduced nucleation overpotentials. The increased current density is therefore, attributed to the following processes: (i) higher concentration of the Z species in the bulk electrolyte; (ii) the reduced electrode surface blocking, enabled by water contents of 20%wt and higher and (iii) the change in Zn solvation environment in the hydrated electrolyte.

To better understand the role of the Z intermediate in Zn deposition, we performed Rotating disk electrode (RDE) voltammetry on a glassy carbon electrode. RDE measurements reported in Fig. 1, (panel D–F) displays similar voltammetric behavior as observed in stationary conditions from our previous study<sup>27</sup> and CVs at a Zn electrode, reported above. Specifically, a cathodic peak appears only during the reverse scan toward positive potential. When the water concentration is kept below 10%, the current density of the reverse cathodic peak decreases as the rotation speed increases. This supports the hypothesis of the formation of a Z intermediate species. When the ligand RO<sup>−</sup> or the intermediate species Z are formed, they are transported away from the electrode surface to the bulk solution by hydrodynamic forces, leading to a decrease in Zn deposition as the rotation speed increases.

At 20% water content, RDE measurements revealed an increase in the cathodic peak current, which grows with increasing rotation speed—contrary to the trend seen in less hydrated electrolytes. This suggests that the Z species are present at higher concentrations or already in the bulk electrolyte, supporting the hypothesis of a higher concentration of RO<sup>−</sup> ligands. These findings align with the mechanistic study by Vieira *et al.*, which observed similar behavior when NaOC<sub>2</sub>H<sub>5</sub> was added to a ChEG DES.<sup>43,44</sup>

Notably, no limiting current plateau was observed, even at higher rotation speeds, possibly indicating a slow adsorption/desorption process at the electrode surface.

Building upon the CVs and RDE results, CA measurements were conducted to provide additional insight into the kinetics of Zn deposition and the role of water in modifying electrochemical processes.

In Fig. 2, potential-time transients obtained by imposing current densities of 0.5 mA cm<sup>−2</sup> and 1 mA cm<sup>−2</sup> for 1800 s are reported. These conditions were selected for comparison with the cycling experiment detailed further on.

The measurements revealed that, in the absence of water, the chronopotentiometry curve exhibited a higher initial potential before transitioning to a lower one. This effect becomes more pronounced with increasing current density (Fig. 2, panel A). Anhydrous DES requires an initial initiation step, which supports the hypothesis of forming an intermediate Z species. This initiation step begins at −1.9 V vs. Ag/AgCl, coinciding with the electrochemical potential window reported in Fig. 1B. The increased concentration of intermediate Zn species in the diffusion layer, due to both the desolvation process and electrolyte reduction, is evident in the chronopotentiometric response. It can be concluded that Zn deposition commences only when a sufficient amount of Z species is formed. These findings confirm the dual role of water in modifying Zn coordination and facilitating Zn deposition, as observed in the voltammetric studies.<sup>45</sup>

To explore from the spectroscopic viewpoint the influence of water on Zn coordination, hydrogen bonds, and its activity, spontaneous Raman spectroscopy (SR), Stimulated Raman spectroscopy (SRS) and Impulsive Stimulated Raman Spectroscopy (ISRS) were carried out. In Fig. 3, spontaneous Raman spectra of DESEG with different water contents are reported. To maintain the concentration of Zn<sup>2+</sup> constant, the hydration level was adjusted by adding a 0.3 M ZnSO<sub>4</sub> solution. Distinct shifts in peak frequencies and intensities are observed in the low-wavenumber region related to  $\nu(\text{Zn}^{2+}\text{-ligand})$  250–350 cm<sup>−1</sup> and  $\nu(\text{SO}_4^{2-})$  920–1000 cm<sup>−1</sup>, as well as in the high-wavenumber region related to  $\nu(\text{O-H})$  3000–3800 cm<sup>−1</sup>. These shifts are indicative of evolving hydrogen bonding networks and solvation dynamics with differing hydration levels.

In a dilute ZnCl<sub>2</sub> aqueous solution, chlorine anions exist as free ions. In such systems, the solvation shell of Zn<sup>2+</sup> is predominantly characterized by water molecules, forming [Zn(H<sub>2</sub>O)<sub>6</sub>]<sup>2+</sup>, which exhibits a Raman peak at ~390 cm<sup>−1</sup>.<sup>46,47</sup> Other possible cations present include [ZnCl(H<sub>2</sub>O)<sub>5</sub>]<sup>+</sup> or

Fig. 2 Chronopotentiograms of 0.3 M ZnSO<sub>4</sub> DES EG with 0%, 10% and 20% water fractions, using a Zn electrode at 25 °C at 1 mA cm<sup>−2</sup> (A) and 0.5 mA cm<sup>−2</sup> (B).

Fig. 3 Spontaneous Raman spectra of DESEG-H<sub>2</sub>O hybrid electrolytes with different wt% (0%, 50%, 65%, 71%, 74%, 79%, 89%, 99% and 100%); the spectra are shifted vertically for clarity.

$[\text{ZnCl}(\text{H}_2\text{O})_3]^+$ , where one chlorine anion is found in the first solvation shell of  $\text{Zn}^{2+}$ . Additionally, various Zn-Cl species may exist in aqueous solution, such as  $\text{ZnCl}_2$ ,  $[\text{ZnCl}_3]^-$ ,  $[\text{ZnCl}_4]^{2-}$ . The  $[\text{ZnCl}_4]^{2-}$  ion predominates when an excess of chloride anions is present, as is the case in ethaline, exhibiting a characteristic peak around 275–290  $\text{cm}^{-1}$ .

In order to explore hydration and ion-pairing in DESEG electrolyte, we compared pure anhydrous ethaline, in which no Zn-ligand signal is present, and anhydrous ethaline with different concentrations of  $\text{ZnSO}_4$ . A  $\text{ZnSO}_4$  (0.3 M) solution, in which no chloride complex formation occurs, was chosen to enable the identification of differences in Raman shift. The

specific choice of sulfate stems from the fact that a polyatomic anion like sulfate with different coordination interaction leads to significant changes in the spectrum of the complexed sulfate. Hence, it becomes feasible to distinguish between bands corresponding to uncomplexed sulfate and those associated with the complexed form.

Spontaneous Raman Spectra of Anhydrous ethaline measured with different  $\text{ZnSO}_4$  concentration are reported in Fig. S2.† Interestingly, at 0.1 M  $\text{ZnSO}_4$  a new peak appears at 279  $\text{cm}^{-1}$ , which is assigned to  $[\text{ZnCl}_4]^{2-}$ .<sup>46,48–53</sup> Raman studies with different concentrations of  $\text{ZnCl}_2$  by Medea *et al.*<sup>50</sup> assigned vibrational modes at 277, 283 and 300  $\text{cm}^{-1}$  to  $[\text{ZnCl}_4]^{2-}$ ,  $[\text{ZnCl}_3]^-$  and  $\text{ZnCl}_2$  respectively. When the water fraction is increased in the eutectic network, the peak at 279  $\text{cm}^{-1}$  is blue shifted (Fig. 4A–C). The blue shifted peak indicates a shorter Zn-Cl bond length, which can be attributed to the formation of lower complex ions: water molecules enter the first sheath of the Zn coordination shell forming  $[\text{ZnCl}_3(\text{H}_2\text{O})]^-$ .

It is worth noting that, increasing the concentration of water in the eutectic electrolyte leads to a notable increase of the fluorescence background in the Spontaneous Raman spectra: this reduces the signal-to-noise ratio, especially affecting the signal in the  $\nu(\text{Zn-ligand})$  range. In response to this challenge, we combined Spontaneous Raman with Stimulated Raman spectroscopy (SRS) and Impulsive Stimulated Raman Spectroscopy (ISRS). In both SRS and ISRS, indeed, the Raman features are engraved on top of the probe beam, thereby enabling efficient suppression of the isotropic fluorescence background (as detailed in the ESI, Fig. S3–S5†).<sup>28,35</sup> In addition, significant signal enhancement is achieved through stimulated excitation of vibrational coherences, leading to faster data acquisition and improved sensitivity.<sup>51</sup> Such advantages make SRS and ISRS

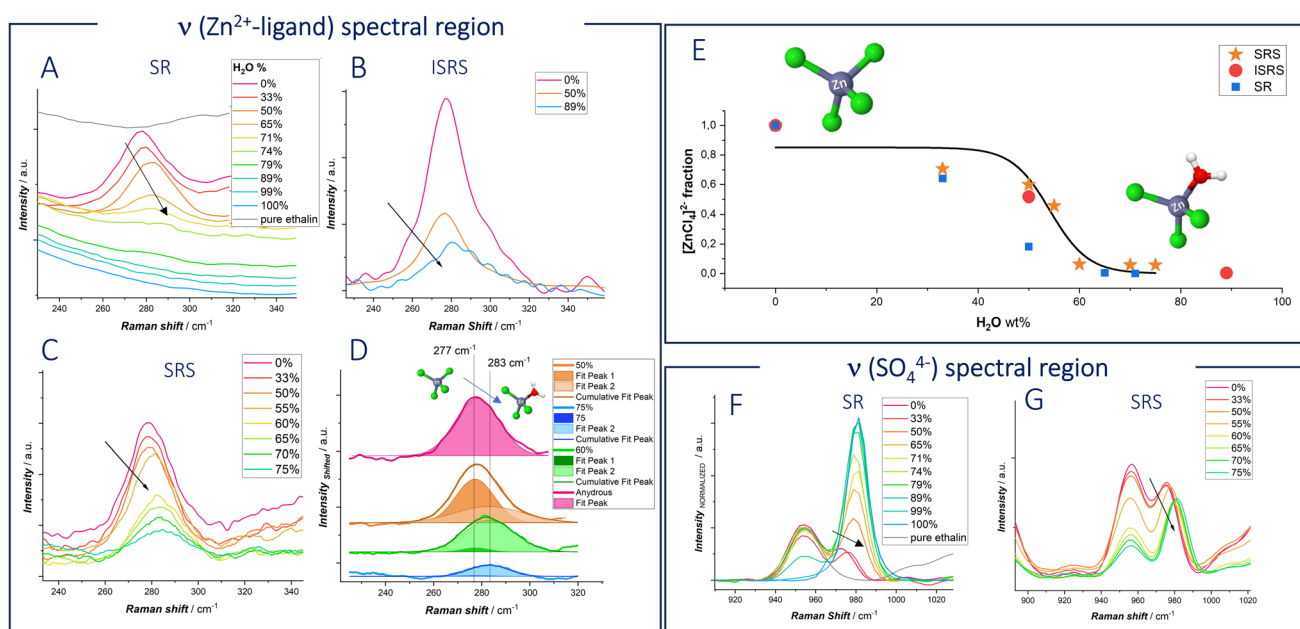

Fig. 4 (A–D)  $\nu(\text{Zn-ligand})$  and (F and G)  $\nu(\text{SO}_4^{2-})$  spectra for pure anhydrous ethaline and DESEG-H<sub>2</sub>O hybrid electrolytes with the indicated water wt%: (A) spontaneous Raman; (B) Impulsive Stimulated Raman Scattering (ISRS); (C) Stimulated Raman Scattering (SRS); (D) fitted SRS curves. (E)  $[\text{ZnCl}_4]^{2-}$  fraction estimated for the fitting of the spectra of panels (A–D). (F) Spontaneous Raman. (G) SRS.

superior for applications requiring rapid and sensitive molecular analysis. We specifically chose these techniques to unravel the vibrational response of the Zn–ligand stretching peak, ensuring more accurate and detailed spectral information.

Also, for SRS and ISRS spectra reported in panels B–D of Fig. 4 and S6† show the same blue shift detected with Spontaneous Raman spectroscopy. Fig. 4E quantifies the fraction of  $[\text{ZnCl}_4]^{2-}$  as a function of water content in the solvent mixture, derived from the fitting of the  $\nu(\text{Zn-ligand})$  bands shown in panels (B–D). Specifically, the  $[\text{ZnCl}_4]^{2-}$  and  $\text{ZnCl}_3^-$  modes at  $277\text{ cm}^{-1}$  and  $283\text{ cm}^{-1}$ , respectively, were fitted with Gaussian functions, and the species fraction was calculated as the ratio of the fitted peak areas. Fit examples are reported for the case of SRS data in Fig. 4D.

The experimental data, gathered from SR, ISRS and SRS, exhibit a sigmoidal trend. At low water content,  $[\text{ZnCl}_4]^{2-}$  is the dominant species, with its fraction decreasing around 50% of water content. It is important to note that ISRS is particularly effective at measuring the Raman peak even at high water concentrations, where other techniques may face challenges due to reduced signal intensity.

In panels (F and G) the SR and SRS Raman peaks centered at *ca.*  $981\text{ cm}^{-1}$ , assigned to the  $\nu(\text{SO}_4^{2-})$  vibration,<sup>52</sup> are found to exhibit a significant red shift between aqueous 0.3 M  $\text{ZnSO}_4$  and 0.3 M  $\text{ZnSO}_4$  in DES EG. This shift indicates stronger coordination in the eutectic electrolyte. Sulfate, which is almost as good an H-bond acceptor as water, can form stronger hydrogen

bonds with EG and  $\text{Ch}^+$ , indicating the presence of distinct complex species rather than hydrated ions. Moreover, upon water addition, a blue shift is observed. The behavior of the sulfate anion mirrors the coordination changes observed with zinc cations. In fact, water molecules hydrate deep eutectic solvents, displacing one or more ligands from the first coordination shell of the ion.

We exploited the high specific sensitivity of Raman spectroscopy to single out the differences in chemical environment of water between the pure aqueous solvent (Fig. 5C and indicated plots of panels (A and B)) and hydrated DES (panels A, B and D of Fig. 5). The Raman O–H stretching band of water was deconvoluted using five Gaussian functions (Fig. 5B) centered at  $3030\text{ cm}^{-1}$  (DAA-OH, single donor–double acceptor),  $3212\text{ cm}^{-1}$  (DDAA-OH, double donor–double acceptor),  $3416\text{ cm}^{-1}$  (DA-OH, single donor–single acceptor),  $3552\text{ cm}^{-1}$  (DDA-OH, double donor–single acceptor), and  $3628\text{ cm}^{-1}$  (free-OH) as previously reported.<sup>53</sup>

Thus, based on the peak positions, five types of water environments in a water-based solution can be assigned, as schematized in Fig. 5C:

- (i) Fully bonded water (DDAA), where one water molecule is involved in four hydrogen bonds (two as a donor and two as an acceptor).
- (ii) Not-fully hydrogen-bonded water (DDA, DA, and DAA).
- (iii) Free water molecules.

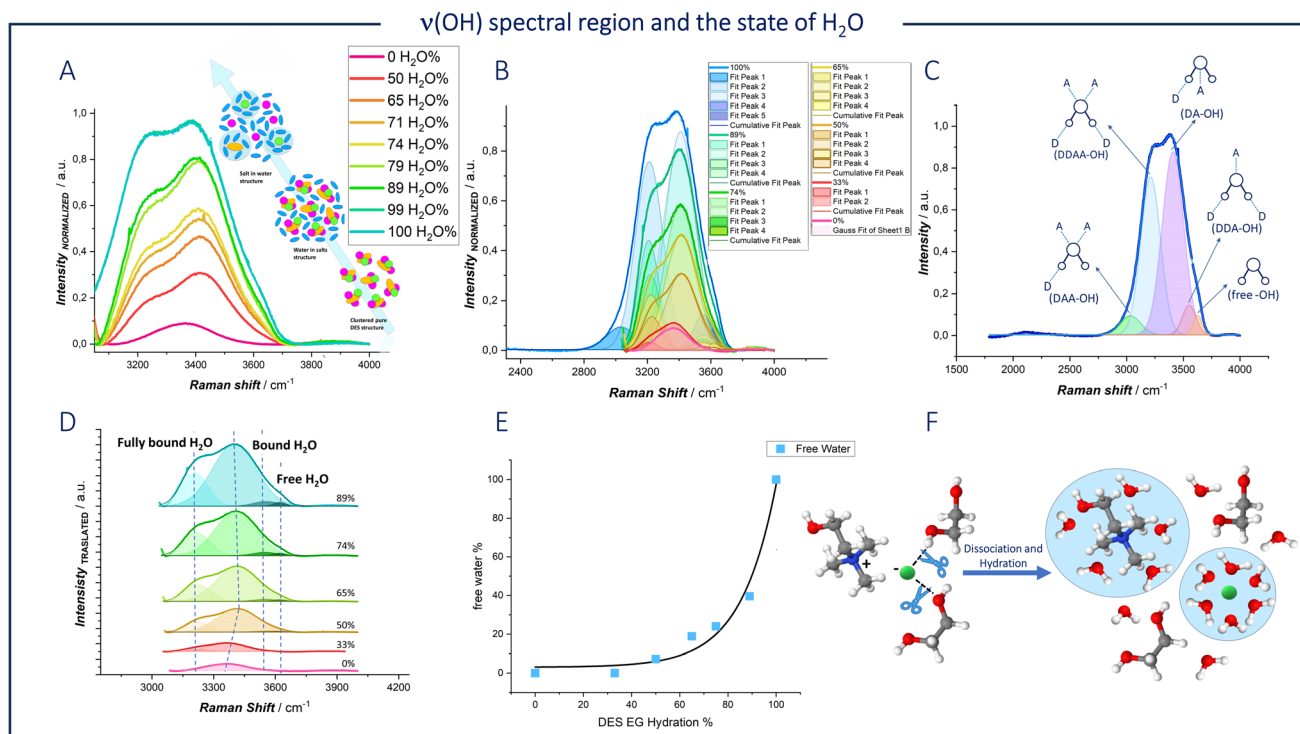

Fig. 5 (A) Spontaneous Raman spectra in the  $\nu(\text{OH})$  region, for DESEG-H<sub>2</sub>O hybrid electrolytes with the indicated water fractions. (B) The fitted Raman spectra of panel (A). (C) Schematic diagram of water environment and Raman peak assignment. (D) Translated fitted Raman spectra of panel (B). (E) The proportions and total of bulk free H<sub>2</sub>O as a function of the water fraction. (F) Schematic of the coordination environment of DESEG before and after hydration. The white, gray, red, blue, green, balls represent hydrogen, carbon, oxygen, nitrogen atoms and chloride anion, respectively.

Hydrogen bonding weakens the covalent O–H bond in water, lowering its vibration frequency. In deep eutectic solvents with a water content below 50%, the free water peak is not observed. As the water content decreases, the clusters of water molecules disintegrate, eliminating the DDAA environment. As dilution proceeds, hydrogen bonds between the components of the DES are broken, forming new bonds between the DES components and water.

At high water concentrations, interstitial water leads to stronger interactions between water molecules and  $\text{Cl}^-$  ions, as well as between water molecules and choline molecules, thereby preventing these components from interacting with each other (Fig. 5F). Although  $\text{Cl}^-$  and  $\text{Ch}^+$  can form stronger hydrogen bonds with water and are thus the first to be solvated in the eutectic network, ethylene glycol contains a large number of hydroxyl groups and can act as both a proton donor and a proton acceptor, bonding with water in multiple ways.<sup>54</sup>

Different solvation regimes are present in the mixtures, with chloride (and the solvent as a whole) becoming partially and then fully hydrated: this corresponds to the transition of the eutectic/ $\text{H}_2\text{O}$  systems from a “water-in-eutectic” to an ordinary “aqueous solution” regime (Fig. 1A).

The fitted  $\nu(\text{OH})$  Raman bands were used to quantify the fraction of the free  $\text{H}_2\text{O}$  environment configuration (Fig. 5E). A

significant decrease of 92.8% in the fitted area of free  $\text{H}_2\text{O}$  can be observed. As shown in Fig. 5D, there is a significant change in the peak related to bound O–H at  $3416\text{ cm}^{-1}$ , which is assigned to the OH group present in both water and DES. During the dilution process, a blue shift is observed when the  $\text{H}_2\text{O}$  percentage is less than 50%. In contrast, a red shift appears when the  $\text{H}_2\text{O}$  percentage exceeds 50%. The same shift was reported by Ying Wang *et al.*<sup>54</sup> for a mixed solution of ethylene glycol and water. The authors correlate this phenomenon with a change in the hydrogen bonding of water related to a transition in the association structure between EG and  $\text{H}_2\text{O}$ .

To summarize, the predominant form of intermolecular hydrogen bonding observed was between the DES components and water, and the dominant Zn solvation structure is  $\text{ZnCl}_4^{2-}$  at water contents lower than 50%. With the progressive addition of water,  $\text{Cl}^-$ ,  $\text{Ch}^+$  and EG molecules still form H-bond with their neighbor  $\text{H}_2\text{O}$ , but there are a large number of water molecules interacting with each other. At the same time, one water molecule enters the first coordination shell of Zn forming  $[\text{ZnCl}_3]^-$ .

In order to clarify the role of surface reactivity of water molecules and the formation of degradation byproducts of organic DES components, SERS was employed: the SERS-active Au electrode was selected as in our previous study.<sup>27</sup> Fig. 6 reports potential-dependent SERS spectra, measured *in situ* in

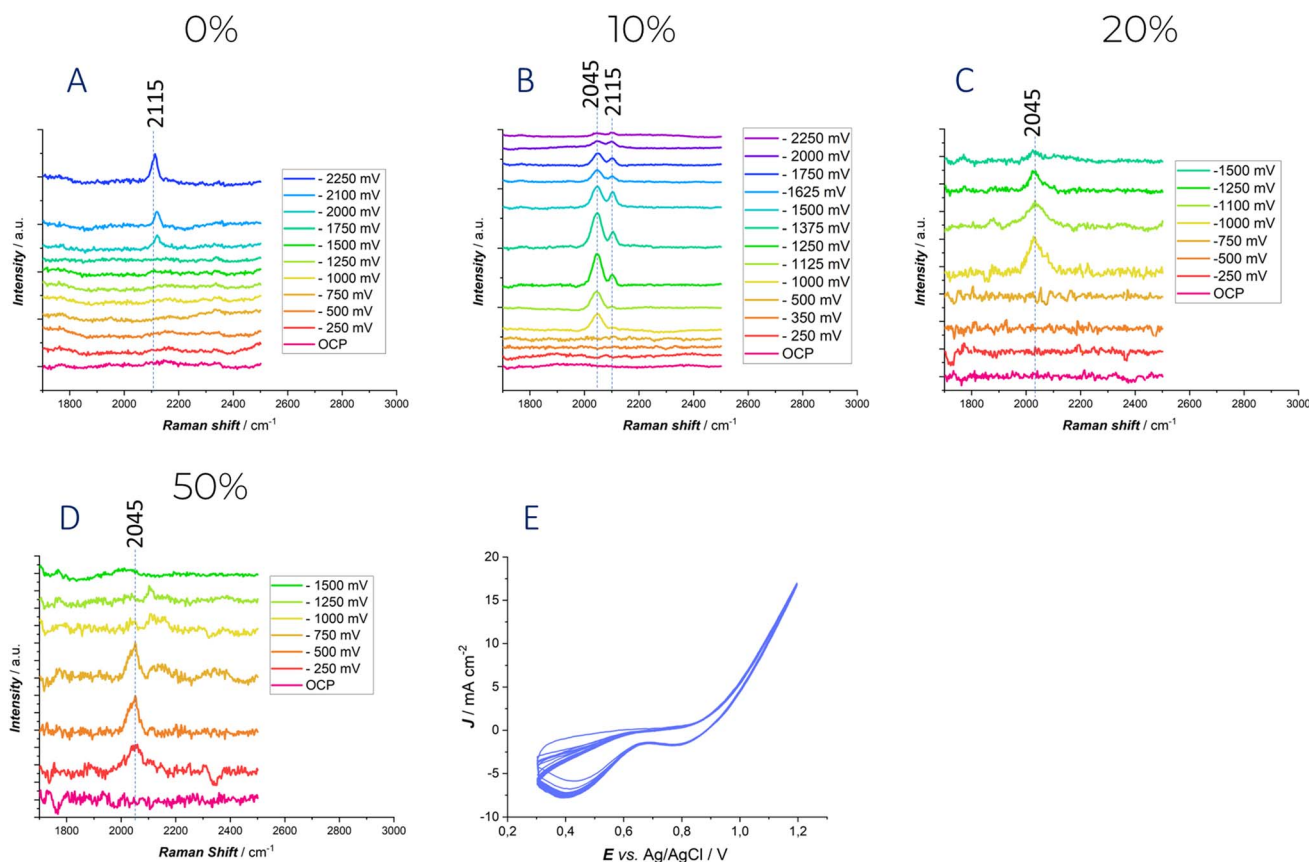

Fig. 6 Potential-dependent *in situ* SERS spectra measured at an ORC-treated polycrystalline Au electrode in contact with the Ethaline DES with the indicated water contents. Panels (A–D) report the spectra recorded in the  $\text{CN}^-$  stretching range for different hydration levels. (E) A typical ORC cycle adopted for the achievement of the SERS effect.

the potential range investigated by CV with DESEG containing different water fractions in the absence of  $\text{Zn}^{2+}$  in solution.

At 0% water content and under polarization in the high cathodic range ( $-2000$  mV) (Fig. 6A), a new peak at  $2115\text{ cm}^{-1}$  is observed, which is characteristic of the  $\nu(\text{C}\equiv\text{N})$  stretching of adsorbed  $\text{CN}^-$ .<sup>27</sup> The potential at which this peak appears correlates well with the electrochemical stability window discussed above. Notably,  $-2$  V is the potential at which the current begins to rise. The presence of the  $\text{CN}^-$  anion was already demonstrated in our previous study<sup>27</sup> and has also been reported in literature on ionic liquids.<sup>55</sup> This can be attributed to the degradation of the choline cation in deep eutectic solvents. Hoffman's elimination or the direct reduction of choline cations is likely to occur a high cathodic potential, leading to the formation of trimethylamine, which can subsequently be deprotonated by either  $\text{OH}^-$  or  $\text{H}^+$ , resulting in the formation of the  $\text{CN}^-$  group.

When the water content is increased to 10%, a distinct peak at  $2045\text{ cm}^{-1}$  is observed at  $-1$  V. This band can be attributed to the Au-H stretching, based on both the polarization conditions and related literature for platinum electrodes.<sup>56</sup> Moreover, in the SERS study by<sup>37</sup> on a gold electrode, a broad band centered between  $2039$  and  $2094\text{ cm}^{-1}$  was similarly assigned to Au-H stretching. As the applied potential is further shifted in the negative direction, the intensity of this peak increases, reflecting a stronger interaction between water and the electrode surface. Additionally, at  $-1125$  mV, the appearance of a peak at  $2115\text{ cm}^{-1}$ , again corresponding to the adsorbed  $\nu(\text{C}\equiv\text{N})$  stretching, is observed.

When the water content is increased further, the only peak detected during polarization corresponds to the Au-H stretch, appearing at  $-1$  V for 20% water content and at  $-250$  mV for 50% water content. The disappearance of the adsorbed  $\nu(\text{C}\equiv\text{N})$  stretching band might be due to the signal reduction due to intense scattering by  $\text{H}_2$  bubbles and/or to the fact the high surface coverage with  $\text{H}^+$  radicals scavenge surface cyanide.<sup>58</sup>

Also in these cases, the results are consistent with the cyclic voltammetry discussed above. The extent of the electrochemical stability window clearly anticorrelates with the water content: this trend that can be tracked from the development of peaks in the  $2000$ – $2150\text{ cm}^{-1}$  range. Water reduction accelerates the decomposition reactions of the choline cation, explaining why the peak related to  $\text{CN}^-$  stretching appears at lower overvoltage.

The stability assessment of Zn anodes in deep eutectic solvent electrolytes with varying water contents was conducted through extensive galvanostatic cycling. Fig. 7 presents the results obtained from galvanostatic charge–discharge (GCD) experiments with a symmetric Zn|Zn cell employing DESEG electrolyte with different water concentrations.

According to our previous study, the absence of water as co-solvent in the electrolyte resulted in high viscosity, low conductivity and reduced diffusivity, leading to lower performance compared to hydrated counterparts.

Notably, the symmetrical cell with 0% water DES electrolyte exhibited poor cycling stability, characterized by elevated overvoltage and irregular chronopotentiometric transient shapes. Cycling lasted approximately 32 days and were terminated by a short circuit, with a voltage excursion of *ca.*  $\pm 600$  mV. The introduction of water into the electrolyte, starting with 10%, significantly improved cyclability. The cell demonstrated an extended cycling life of approximately 50 days, although with only a marginal reduction in overvoltage compared to the anhydrous electrolyte. Chronopotentiometric transients continued to show irregularities, especially in the cathodic phase, with a significant decrease in overvoltage observed after 100 hours. Additionally, the transients exhibited non-symmetrical behavior between the cathodic and anodic phases. In this case the cell failure was due to passivation, as discussed in detail in ref. 59 and 60.

Further increasing the water content to 20%, notably enhanced cell performance was obtained. With this composition, the cycling duration increased impressively to 82 days,

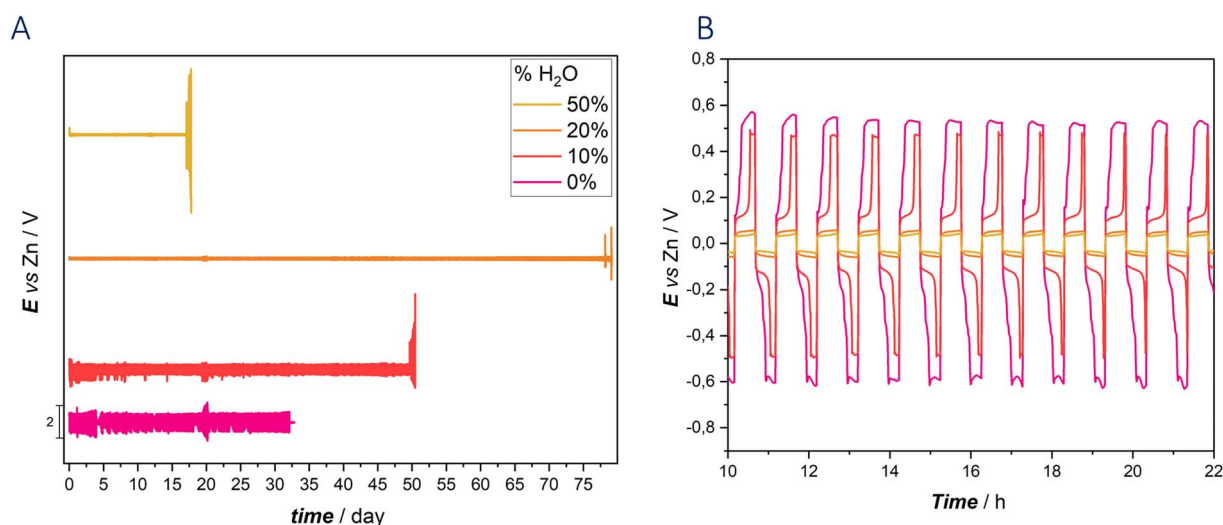

Fig. 7 (A) Galvanostatic charge–discharge cycling experiments carried out with Zn symmetric CR2032 coin cells with the indicated DES hydration levels. (B) Chronopotentiometric transient shapes, extracted from the data of panel (A).

accompanied by remarkably low overpotential ( $\pm 60$  mV voltage excursion) and sustained transient shape stability. The chronopotentiometric transients remained stable from the beginning to the end of the test, highlighting a high reversibility of the plating/stripping process. However, exceeding the 20% water threshold disrupted the DES network, transforming the eutectic into an aqueous solution. This transition was evident in the performance of the 50% water DES, where cycling stability was maintained with minimal overpotential until passivation occurred after 20 days of cycling. GCD cycling of cells replicates are reported in Fig. S7.†

To our knowledge, these results represent the 3rd best performance reported to date, as summarized in Table 1. These findings underscore the role of water content in DES electrolytes, with optimal hydration levels significantly enhancing battery performance and stability, while excessive water content leads to a transition to aqueous electrolytes and eventual passivation. Additionally, DES systems exhibit consistent and stable potential transient shapes, with notable symmetry observed in the charge and discharge transients, particularly evident in the 20% and 50% DES configurations.

The controlled addition of water in DES tunes the conductivity of the electrolyte, as evidenced by the difference in ohmic resistance observed in the cell operating with anhydrous DES.

The overvoltages recorded during cycling are consistent with those observed in the cathodic branch of the cyclic voltammograms and with the potential-time transient of CA experiments.

## 4. Conclusions

In this study, the electrochemical behavior of zinc in ethaline DES with varying degrees of hydration was systematically investigated with electrochemical and vibrational spectroscopy methods. The findings reveal that the addition of water significantly influences the electrochemical properties and modifies the Zn deposition process. At low hydration levels, the DES maintains its structure, characterized by high viscosities and slow kinetics. As the water content is increased, viscosity decreases, enhancing ion mobility. Notably, the coordination environment of zinc shifts from  $[\text{ZnCl}_4]^{2-}$  in anhydrous DES to  $[\text{ZnCl}_3(\text{H}_2\text{O})]^-$  and eventually to more hydrated species at higher water contents. These changes lead to improved zinc plating/stripping efficiency and cycling stability.

Raman spectroscopy, employed combining SR, SERS, SRS and ISRS techniques, confirmed the formation of different zinc-ligand complexes and the critical role of water in modifying the DES structure. The optimized hydration level was found to be around 20 wt%, balancing the advantages of reduced viscosity and enhanced conductivity without compromising the DES stability and keeping the concentration of free active water low. Although at 20 wt% the coordination of Zn was found to be  $[\text{ZnCl}_4]^{2-}$ , that has a higher dissociation energy compare to  $[\text{ZnCl}_3(\text{H}_2\text{O})]^-$ , the impact on the formation of the Z intermediate species that undergo reduction results in a completely different CV behavior related to the anhydrous case. In particular, the cathodic deposition peak was already present in the forward scan.

This work underscores the potential of hydrated DES as highly prospective electrolytes for ZIBs, offering a flexible tool for controlling zinc electrochemistry and enhancing their efficiency and durability. It is important to note that the behavior of water in DES is strongly influenced by the specific components and their hydrogen bond network. Therefore, our findings, that highlight the optimal performance at 20 wt% water in this system, cannot be directly transferred to any DES formulation.

Additionally, this study represents the first attempt to analyze the anomalous cyclic voltammetry behavior of zinc plating in hydrated DES, providing new insights into the electrochemical processes involved. The nuanced understanding of the interplay between solvent composition, Zn solvation, and electrodeposition mechanisms paves the way for the development of more efficient and sustainable ZIB technologies.
