## Synthesis and photocatalytic CO<sub>2</sub> reduction performance of aminated coal-based carbon nanoparticles

Halidan Maimaiti, \* Abuduheiremu Awati, Dedong Zhang, Gunisakezi Yisilamu and Bo Xu

To obtain high-efficiency, low-cost, environmentally friendly carbon-based photocatalytic material, we synthesized coal-based carbon dots with sp<sup>2</sup> carbon structure and multilayer graphene lattice structure by the hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>) oxidation method to strip nano-scale crystalline carbon in the coal structure and link with oxygen-containing groups such as the hydroxyl group. N, S co-doped aminated coal-based carbon nanoparticles (NH<sub>2</sub>-CNPs) were then obtained by thionyl chloride chlorination and ethylenediamine passivation. The physical properties and chemical structure of the synthesized NH<sub>2</sub>-CNPs were studied and the photocatalytic CO<sub>2</sub> reduction performance was tested. The results show that NH<sub>2</sub>-CNPs are vesicle-type spherical particles with particle size of 42.16 ± 7.5 nm and have a mesoporous structure that is capable of adsorbing CO<sub>2</sub>. A defect structure was formed on the surface of the NH<sub>2</sub>-CNPs due to the doping of N and S elements, thereby significantly improving the ability to photogenerate electrons under visible light along with the ability to efficiently separate the photo-generated carriers. The photocatalytic reduction products of CO<sub>2</sub> over NH<sub>2</sub>-CNPs were CH<sub>3</sub>OH, CO, C<sub>2</sub>H<sub>5</sub>OH, H<sub>2</sub> and CH<sub>4</sub>. After 10 hours of reaction, the total amount of products was 807.56 μmol g<sup>-1</sup> cat, the amount of CH<sub>3</sub>OH was 618.7 μmol g<sup>-1</sup> cat, and the calculated selectivity for conversion of CO<sub>2</sub> to CH<sub>3</sub>OH was up to 76.6%.

## 1. Introduction

The photocatalytic reduction of CO<sub>2</sub> into hydrocarbon fuels has motivated the research and development of various potentially high-efficiency photocatalysts. The joint efforts of scholars around the world have resulted in new photocatalytic materials for photocatalytic reduction of CO<sub>2</sub>.<sup>1</sup> However, most of the developed catalysts are noble metal- and metal oxide semiconductor-based photocatalysts, such as Ag, TiO<sub>2</sub> and ZnO, *etc.*, which have wide bandgaps, are expensive, show low efficiency for visible light utilization, and pollute the environment. As environmentally friendly substances, carbon-based nanomaterials such as graphene, carbon nanoparticles and activated carbon are abundant and easy to obtain, with low cost and low toxicity.<sup>2</sup> Carbon nanoparticles (CNPs) are a class of zero-dimensional fluorescent nanomaterials that were accidentally discovered by Scrivens *et al.* during the separation and purification of single-wall carbon nanotubes.<sup>3</sup> CNPs have fluorescence properties like traditional quantum dots and are also excellent electron acceptors and donors. After being excited by light, CNPs can generate electrons and holes and, at the same time, can suppress the combination of the photogenerated

electrons and holes by their own surface defects.<sup>4-6</sup> Therefore, they can be used as carriers for photocatalytic materials such as noble metals or semiconductors or can be used as a photocatalyst after being modified by hetero elements.<sup>7-11</sup>

Coal is a natural and inexpensive carbon source, whose microstructure contains amorphous carbon regions consisting of aliphatic groups and nanoscale crystalline carbon formed by polyaromatic groups.<sup>12</sup> The crystalline carbon regions are abundant and each crystalline carbon has the size of a quantum dot, suitable for obtaining CNPs by various methods.<sup>13,14</sup> In our previous study,<sup>15-17</sup> we prepared coal-based CNPs used HNO<sub>3</sub> pretreated coal samples from the Wucaiwian coalmine in Xinjiang, China. We stripped crystalline carbon from the coal by acid oxidation and hydrogen peroxide oxidation methods and linked oxygen-containing groups such as hydroxyl groups on the CNPs. We found that the prepared coal-based CNPs had a multi-layered graphene structure with sp<sup>2</sup> carbon and also contained some metal and non-metallic elements such as Fe, Ca, Al, Si, K, S, *etc.*, thereby having the unique photoelectric properties of metal oxide semiconductor materials.

Modification of carbon nanomaterials and metal oxide semiconductors by doping (especially doping with non-metallic elements such as N, S) is a method for controlling the photoelectric properties of the products. For carbon nanomaterials, the sp<sup>2</sup> hybrid carbon skeleton can be doped to obtain unpaired

*Institute of Chemistry and Chemical Industry, Xinjiang University, Urumqi 830046, Xinjiang, China. E-mail: m15899160730@163.com*

electrons, thereby generating a delocalized  $\Pi$  negative charge system and promoting the electron transport properties of the materials.<sup>18</sup> For metal oxide semiconductors, creating states in the band gap that absorb visible light by doping can improve the visible light efficiency of the materials.<sup>19</sup> Since coal-based CNPs have the characteristics of both general carbon nanomaterials and metal oxide semiconductors, they are expected to simultaneously increase their electron transport properties and visible light efficiency if they are doped with N and S elements. Thus, in this paper, sulfonyl chloride chlorination and ethylene diamine passivation were adopted to dope the synthesized CNPs with nitrogen and sulfur, and aminated coal-based carbon nanoparticles ( $\text{NH}_2\text{-CNPs}$ ) were obtained. The structure and photocatalytic  $\text{CO}_2$  reduction performance were investigated.

## 2. Experimental section

### 2.1 Raw materials and reagents

The coal samples were acquired from Wucaiwang coalmine in Zhundong coalfield, Xinjiang, China. The samples were ground and filtered by a 200 mesh, followed by drying at 105 °C for 4 h. The analytical grade sulfonyl chloride ( $\text{SOCl}_2$ ) was purchased from Aladdin Reagent Co. Ltd. The analytical grade diamine (EDA) was purchased from Tianjin Zhiyuan Chemical Reagent Co. Ltd. Analytical grade DMF, THF,  $\text{H}_2\text{O}_2$ , and  $\text{HNO}_3$  were purchased from common chemical stores.

Ready-to-use dialysate bags (intercepted molecular weight of 500–1000, Spectrum Labs, U.S.) were purchased from Shanghai Tong Shan Biological Science and Technology Co., Ltd.

### 2.2 Preparation of coal-based CNPs

Reflux treatment was conducted on coal samples from Wucaiwang, Xinjiang with 2.5 M  $\text{HNO}_3$  for 24 h. The pre-treated samples were placed in a ball mill with distilled water, and ground for 3 h at room temperature and 600 rpm. After drying, 0.5 g of ultra-fine coal powder was dispersed in 10 mL of deionized water by sonication, then 30 mL of 30%  $\text{H}_2\text{O}_2$  was added to the solution, followed by constant magnetic stirring and reaction at 85 °C for 3 h (5 mL of 30%  $\text{H}_2\text{O}_2$  was added to the solution every 10 min for a total of four times). After the reaction stopped, the reaction liquid was transferred to a centrifuge tube for centrifuge separation (10 000 rpm for 10 min). The supernatant was blown dry by  $\text{N}_2$ , and the black-brown coal-based CNPs were obtained.

### 2.3 Fabrication of $\text{NH}_2\text{-CNPs}$

CNPs (1 g) were placed in a reaction bottle with 20 mL DMF and dispersed by sonication for 2 h at room temperature. After the CNPs were fully dispersed to form a suspension, 15 mL of  $\text{SOCl}_2$  was added to the solution, followed by reflux-stirring and reaction for 12 h at 65 °C. DMF and unreacted  $\text{SOCl}_2$  were removed by centrifugation. The reaction liquid was washed twice with THF to obtain the chloridized intermediate CNPs-Cl and mixed with 30 mL EDA for reflux reaction for 12 h at 130 °C. The temperature of the reaction liquid was decreased to 60 °C,

and 30 mL of distilled water was added to the mixture with constant stirring for 3–4 hours. Next, the reaction liquid was centrifuged at 10 000 rpm for 10 min. The supernatant was placed in a dialysate bag and dialyzed for 72 h (with constant water changing) and the aminated coal-based CNPs ( $\text{NH}_2\text{-CNPs}$ ) water dispersion was obtained. Finally, the  $\text{NH}_2\text{-CNPs}$  were separated by blowing dry the solution with  $\text{N}_2$ .

### 2.4 Structural characterization of the product

An H-600 transmission electron microscope (TEM) was employed to measure the morphology of the product. The elemental analysis was performed by an EDX energy spectrometer (HITACHI-SU8010). The thermogravimetric (TG-DTG) analysis was performed by a thermal analyzer (PE-DTA/1700) with temperature scanning range of 25–800 °C. The XRD patterns of the product were acquired by an X-ray diffractometer (M18XHF22-SRA). The experimental conditions were as below: Cu  $\text{K}\alpha$  radiation ( $\lambda = 0.154056$  nm), and scan range  $2\theta = 10\text{--}80^\circ$ . The confocal Raman spectra of the product were acquired by a Raman spectrometer (BRUKER VERTEX 70). The  $\text{N}_2$  adsorption–desorption performance was tested by a specific surface and aperture distribution meter (Autosorb-IQ2), and the specific surface and aperture distribution were calculated by the BET and BJH method. The FTIR spectrum of the product was obtained by a Fourier transform infrared spectrometer (FTIR, Bruker-EQUINOX 55). The surface states of the product were analyzed by an X-ray photo-electron spectrometer (XPS, ESCALAB 250). The  $\text{CO}_2$  temperature programmed desorption performance ( $\text{CO}_2\text{-TPD}$ ) was measured by a TP-5080 automatic adsorption–desorption dynamic analyzer. The ultraviolet-visible diffuse reflection spectrum (UV-vis DRS) of the product was measured by a UV-vis DRS spectrometer (Shimadzu UV-3100). The electrochemical impedance (EIS) and photoionization density were measured by an electrochemical workstation (CHI 660C).

### 2.5 Photocatalytic $\text{CO}_2$ reduction by visible light

$\text{NH}_2\text{-CNPs}$  (0.2 g) were added to 100 mL of 0.1 M NaOH solution and dispersed by sonication for 15 min in the dark. The suspension was transferred to a quartz bottle in a photocatalytic reduction reactor, as shown in Fig. 1.

The system was placed under vacuum several times to remove air, and high-purity  $\text{CO}_2$  gas was flowed into the suspension at 1 atm with stirring (flow rate of  $\text{CO}_2$  was 20  $\text{mL min}^{-1}$  for 30 min). Next, the whole reaction system was sealed, and illuminated with a 300 W xenon lamp (with a UV cut-off filter to obtain visible light with wavelength over 420 nm) to start the photocatalytic  $\text{CO}_2/\text{H}_2\text{O}$  reduction reaction. After reaction for 6 h, the liquid and gas products were acquired separately and subjected to  $^1\text{H}$  NMR and GC-MS to identify the species generated in the photocatalytic  $\text{CO}_2$  reduction by  $\text{NH}_2\text{-CNPs}$ . The above  $\text{CO}_2/\text{H}_2\text{O}$  photocatalytic reduction was then repeated, and the samples were acquired every 2 h and injected into a gas chromatograph; the liquid and gas products were analyzed by the standard curve method (liquid phase: FID detector, PEG-21 filling column, gas phase: TCD detector, TDX-01 filling column).

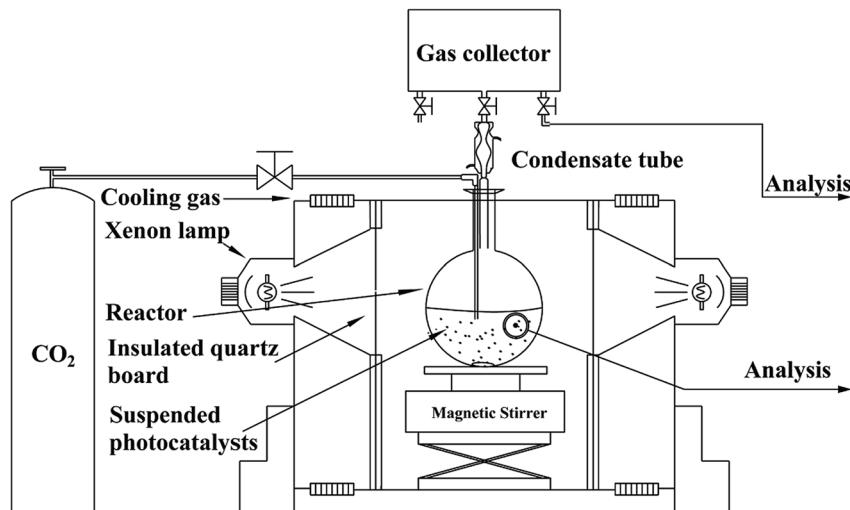

Fig. 1 Schematic of the experimental setup for the photoreduction of  $\text{CO}_2$  with  $\text{H}_2\text{O}$ .

### 3. Results and discussions

#### 3.1 Structure of $\text{NH}_2\text{-CNP}$ s

According to Fig. 2a, coal powder has an irregular size distribution and shape, and it cannot be dispersed in water. However, the CNPs synthesized by  $\text{H}_2\text{O}_2$  have good water dispersion and spherical shape with a diameter of  $4.51 \pm 0.82 \text{ nm}$  (Fig. 2b). The high magnification TEM image (inset) shows that the surface of the CNPs has clear lattice strips. The spacing between the strips is  $0.21 \text{ nm}$ , close to the (100) plane of graphite,<sup>20</sup> indicating that the coal-based CNPs have a graphite-like crystalline carbon structure. It can be seen from Fig. 2c that the  $\text{NH}_2\text{-CNP}$ s are spherical particles with vesicle structure, formed by EDA linking and entangling with CNPs treated by  $\text{SOCl}_2$ ; the particle size of  $42.16 \pm 7.5 \text{ nm}$  is larger compared to the CNPs. The  $\text{NH}_2\text{-CNP}$ s can also be uniformly dispersed in water.

From the EDX results for the coal powder, product CNPs and  $\text{NH}_2\text{-CNP}$ s shown in Table 1, it can be seen that the O and N content in the coal-based CNPs are significantly higher compared to the coal powder, while the C content is decreased. This could be the result of the crystalline carbon being stripped out from the pulverized coal during the  $\text{HNO}_3$  pretreatment, ball milling, tank grinding, and  $\text{H}_2\text{O}_2$  oxidation processes, and

linked to N and O containing groups such as  $-\text{NO}_3$ ,  $-\text{COOH}$ ,  $-\text{OH}$ . Compared to CNPs,  $\text{NH}_2\text{-CNP}$ s have lower inorganic particle content and apparently higher N, S, and Cl content, which is due to the aminated reaction.

Fig. 3A shows the TG-DTG results for coal powder, CNPs, and  $\text{NH}_2\text{-CNP}$ s. We can see from the published literature<sup>21</sup> that the first weight loss peak of coal powder under  $100 \text{ }^\circ\text{C}$  is caused by water volatilization, and the second peak at  $445 \text{ }^\circ\text{C}$  corresponds to the weight loss peak of devolatilization during the pyrolysis process. As the temperature increases, especially exceeding  $600 \text{ }^\circ\text{C}$ , the weight loss is relatively flat, mainly caused by the polycondensation stage.

The coal-based CNPs also showed a peak for the loss of water under  $100 \text{ }^\circ\text{C}$  but there was also a large weight loss peak at  $288 \text{ }^\circ\text{C}$ , which was obviously different from the weight loss behavior of raw coal, corresponding to the volatilization of small molecular compounds and the decomposition or dehydration of oxygen-containing groups such as hydroxyl or carboxyl groups.<sup>22</sup> This indicates that a large amount of active oxygen-containing functional groups appeared in the coal structure as a result of oxidative stripping by  $\text{H}_2\text{O}_2$ . In addition, the coal-based CNPs showed a weight loss peak between  $500\text{--}600 \text{ }^\circ\text{C}$ , corresponding to the condensation and

Fig. 2 TEM images of (a) coal powder, (b) as-grown CNPs and (c)  $\text{NH}_2\text{-CNP}$ s.

Table 1 Elemental analysis data for the coal, CNPs and NH<sub>2</sub>-CNPs

Sample	Processing method	Elemental analysis, <sup>a</sup> w%								
		C	N	O	Al	Si	S	Ca	Fe	Cl
Coal powder	Coal samples were ground and filtered by a 200 mesh	75.04	0.58	17.79	0.89	3.35	0.52	0.71	1.12	0

<sup>a</sup> By EDX.

dehydrogenation of the aromatic structures in the coal; the peak position is lower than the pyrolysis temperature of the coal powder (600–800 °C). The possible reason is that the CNPs contain more oxygen-containing groups, which can induce pyrolysis of the organic compounds, thereby lowering the pyrolysis temperature.<sup>23</sup> The results indicate that the coal-based CNPs obtained by the H<sub>2</sub>O<sub>2</sub> oxidation method mainly contain aromatic structures linked by oxygen-containing groups.

The primary weight loss of NH<sub>2</sub>-CNPs has four stages. The first stage occurs below 100 °C with a loss amount of 2.84%, which is attributed to the water in the sample. The second stage happens at around 192 °C with a loss of 9.63%, corresponding to the heat cracking of EDA groups linked to the CNPs surface.<sup>24</sup> In the third stage, the TG loss is 8.22%, which occurs at around 267 °C and can be attributed to the decomposition of oxygen-containing groups such as carboxyl and hydroxyl into CO<sub>2</sub> or CO at high temperatures.<sup>25</sup> The oxygen-containing groups were introduced in the synthesis process (such as coal pre-treatment by HNO<sub>3</sub> or H<sub>2</sub>O<sub>2</sub> oxidation). The fourth stage happened at near 551 °C with a loss amount of 28.28%, corresponding to the

condensation dehydrogenation of the aromatic structure into semicoke.<sup>16</sup> Above 600 °C, there was 57.30% undecomposed remnant, which was made up of the graphitized carbon and a small amount of inorganic particles in NH<sub>2</sub>-CNPs.<sup>26</sup> The TG-DTG results further prove that the CNPs were successfully aminated. Fig. 3B shows the XRD patterns of coal powder, CNPs and NH<sub>2</sub>-CNPs. According to the figure, CNPs demonstrate a broad diffraction peak at 15–40°, corresponding to the (002) crystal plane of graphite;<sup>27</sup> this characteristic peak does not appear in the XRD pattern of the coal sample. After amination, the corresponding graphite (002) peak in the NH<sub>2</sub>-CNPs shifted toward lower angle. This is because the surface of CNPs is linked to NH<sub>2</sub>- and other groups containing N and S, leading to the larger particle size of NH<sub>2</sub>-CNPs compared to CNPs.

Raman spectrometry is an effective method for evaluating the structure and performance of carbon nanoparticles. As shown in the Raman spectrum in Fig. 3C, both CNPs and NH<sub>2</sub>-CNPs demonstrate two obvious peaks at 1350 and 1580 cm<sup>-1</sup>, corresponding to the D band and G band, respectively; however, the coal powder does not display the characteristic peaks. The D

Fig. 3 Physical characterizations of coal powder, CNPs, and NH<sub>2</sub>-CNPs. (A) TG-DTG; (B) XRD; (C) Raman; (D) BET.

band is related to the defects in carbon materials, and the G band reflects the  $sp^2$  hybrid carbon atom content in carbon material.<sup>28</sup> The ratio of the peak intensity ( $I_D/I_G$ ) between the D band and G band can be used to evaluate the graphitization and defects of the carbon material. Using the raw data from Fig. 3C, the calculated  $I_D/I_G$  for CNPs and NH<sub>2</sub>-CNPs is 0.76 and 0.98, respectively. The  $I_D/I_G$  was apparently increased after the CNPs were aminated, suggesting their high microstructural integrity. The aminated material also has defect edges, which favor the effective separation of photogenerated electrons and holes,<sup>29</sup> leading to enhanced photocatalytic CO<sub>2</sub> reduction activity.

N<sub>2</sub> adsorption-desorption tests were performed on coal powder, CNPs and NH<sub>2</sub>-CNPs. The specific surface area of the sample was calculated using the BET equation, and the pore size and distribution were calculated by the BJH equivalent cylinder model; the results are shown in Fig. 3D. The hysteresis loop of coal powder is not obvious, indicating that coal has a complex pore structure that cannot be described by the BET theory. The adsorption isotherms of the coal-based CNPs belong to I-type isotherms, indicating that CNPs are microporous structural materials. The N<sub>2</sub> adsorption-desorption isotherms for NH<sub>2</sub>-CNPs are type-IV isotherms, indicating the mesoporous structure. From the pore distribution graph (inset), the CNPs have a pore size of 3–12 nm, and NH<sub>2</sub>-CNPs have small pores of 2–9 nm and large pores of 10–60 nm. The corresponding BET specific surface areas are 29.36 m<sup>2</sup> g<sup>-1</sup> for CNPs, and 172.65 m<sup>2</sup> g<sup>-1</sup> for NH<sub>2</sub>-CNPs. The total pore volume for CNPs and NH<sub>2</sub>-CNPs is 0.0114 cm<sup>3</sup> g<sup>-1</sup> and 0.320 cm<sup>3</sup> g<sup>-1</sup>, respectively. Generally, a larger specific surface area and pore volume are favorable for reactant adsorption, which can significantly enhance the photocatalytic activity.<sup>30</sup>

Fig. 4A shows the infrared spectrum of CNPs and NH<sub>2</sub>-CNPs. The CNPs synthesized by H<sub>2</sub>O<sub>2</sub> oxidation and separation show the stretching-vibration peak of the hydroxyl groups at

3400 cm<sup>-1</sup> (curve a). At 1635 cm<sup>-1</sup>, the peak corresponds to the stretching-vibration absorption peak of  $-C-O-$ . The peak at 1350 cm<sup>-1</sup> corresponds to the stretching-vibration peak of COO<sup>-</sup>. The peak at 1093 cm<sup>-1</sup> is the stretching-vibration peak of C-O. The peak at 797 cm<sup>-1</sup> is the stretching-vibration peak of C-NO<sub>2</sub>. The absorption peak at 605 cm<sup>-1</sup> corresponds to inorganic particles. For NH<sub>2</sub>-CNPs, besides the above characteristic peaks, there are apparent amido (CONH<sup>-</sup>) peaks at 3245 and 2922 cm<sup>-1</sup>. At 1520, 1443 and 1219 cm<sup>-1</sup>, the absorption peaks correspond to the amide I band, amide II band and amide III band, respectively. The peak at 583 cm<sup>-1</sup> corresponds to the O-S absorption peak. The results suggest that CNPs have successfully reacted with EDA to give the aminated product NH<sub>2</sub>-CNPs. There is no apparent absorption peak for inorganic particles or free ethylenediamine, suggesting the inorganic content was lowered and the EDA was removed by dialysis.

XPS can be used to detect the valence states of elements in nanomaterials. To further determine the product chemical structure, we used XPS to analyze the surface states of CNPs and NH<sub>2</sub>-CNPs, as shown in Fig. 4(B–F). According to the full XPS spectra of CNPs and NH<sub>2</sub>-CNPs (Fig. 4B), the two products show similar XPS patterns, with four characteristic peaks at 160.0, 286.0, 401.0 and 530.9 eV, corresponding to S<sub>2p</sub>, C<sub>1s</sub>, N<sub>1s</sub> and O<sub>1s</sub>. The results show that CNPs and NH<sub>2</sub>-CNPs are mainly composed of C, N, O, and S, and the N and S contents in NH<sub>2</sub>-CNPs are apparently higher as compared to those in CNPs. The O content of NH<sub>2</sub>-CNPs is lower than CNPs, possibly due to the replacement of oxygen-containing groups by NH<sub>2</sub>- groups. Fig. 4C shows the high-resolution XPS spectrum of C<sub>1s</sub> for CNPs and NH<sub>2</sub>-CNPs. The NH<sub>2</sub>-CNPs have five splitting peaks at 284.8 eV, 286.1 eV, 287.3 eV, 288.0 eV and 292.4 eV, corresponding to C-C, C-O, C-O-C, C=O and O=C-O bonds, respectively. The C-C, C-O and C=O bond have high content and are consistent with the high-resolution XPS spectrum of C<sub>1s</sub>

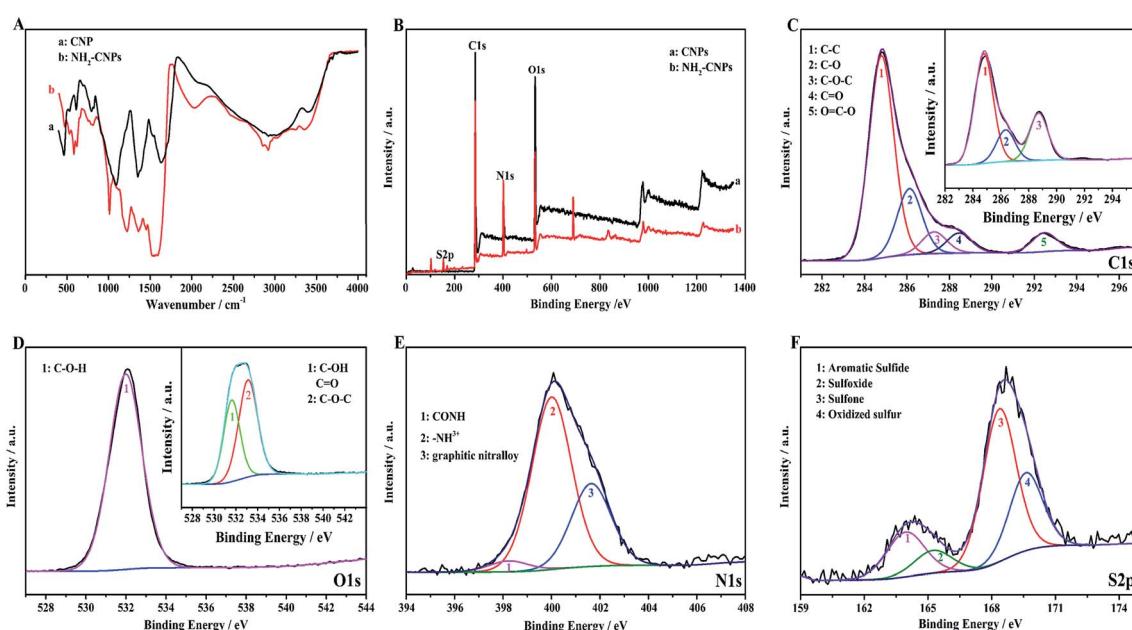

Fig. 4 Structural characterizations of CNPs and NH<sub>2</sub>-CNPs: (A) FT-IR spectra; (B–F) XPS spectra.

for CNPs (inset). This shows that the skeleton of the  $\text{NH}_2$ -CNPs comes from CNPs. Fig. 4D shows the high-resolution XPS spectrum of  $\text{O}_{1s}$  for CNPs and  $\text{NH}_2$ -CNPs. The CNPs have peaks at 530.0 eV and 532.8 eV, which correspond to the C–O and C=O groups of the graphene structure (inset).<sup>31</sup>  $\text{NH}_2$ -CNPs have a single peak between 530.0 eV and 532.8 eV, which is attributed to C–O–H. This suggests that the oxygen content is lowered during amination. Fig. 4E shows the high-resolution XPS spectrum of  $\text{N}_{1s}$  for  $\text{NH}_2$ -CNPs. There are three splitting peaks at 398.28 eV, 399.98 eV and 401.68 eV. The peaks at 398.28 eV and 399.98 eV have low binding energies, corresponding to the amide bond (CONH) and an amine with a positive charge ( $-\text{NH}^{3+}$ ).<sup>32</sup> The peak at 401.68 eV corresponds to graphite nitrogen, which is formed by replacing the carbon atoms with nitrogen atoms.<sup>33</sup> Fig. 4F is the high-resolution XPS spectrum of  $\text{S}_{2p}$  in  $\text{NH}_2$ -CNPs. It can be seen that the products have four types of S structure. The peaks at 163.96 eV, 164.9 eV, 168.4 eV, and 169.7 eV correspond to C–S–C, C=S, C–SO<sub>2</sub>–C, and C–SO<sub>3</sub>–C groups,<sup>34–37</sup> respectively.

### 3.2 Photocatalytic $\text{CO}_2$ reduction performance by $\text{NH}_2$ -CNPs

To confirm the photocatalytic products and selectivity of the  $\text{NH}_2$ -CNPs, we used <sup>1</sup>H NMR and GC-MS to analyze the liquid and gas products obtained after reaction for 6 hours.

Fig. 5A shows the <sup>1</sup>H NMR results for the liquid products from the photocatalytic  $\text{CO}_2$  reduction by  $\text{NH}_2$ -CNPs. The single peak at  $\delta = 3.34$  ppm is the chemical shift of hydrogen protons at  $-\text{CH}_3$  of  $\text{CH}_3\text{OH}$ . The triple peak at  $\delta = 1.17$  ppm and the quadruple peak at  $\delta = 3.67$  ppm represent the hydrogen protons at  $-\text{CH}_2$  of  $\text{CH}_3\text{CH}_2\text{OH}$ . The single peak at  $\delta = 4.79$  ppm is the  $\text{D}_2\text{O}$  solvent. This result shows that the liquid products of photocatalytic  $\text{CO}_2$  reduction are  $\text{CH}_3\text{OH}$  and  $\text{C}_2\text{H}_5\text{OH}$ .

We also identified the gas products by GC-MS. The results show that the gas products of photocatalytic  $\text{CO}_2$  reduction by  $\text{NH}_2$ -CNPs contain  $\text{H}_2$ , CO, and  $\text{CH}_4$ . Fig. 5B shows the GC-MS results of the gas products when we used the isotopic marker <sup>13</sup>CO<sub>2</sub> as the only carbon source in the system for photocatalytic  $\text{CO}_2$  reduction. According to the results,  $m/z = 17$  and 29 represent <sup>13</sup>CH<sub>4</sub> and <sup>13</sup>CO, respectively, which indicate that the CO and  $\text{CH}_4$  come from photocatalytic  $\text{CO}_2$  reduction by  $\text{NH}_2$ -CNPs.

Fig. 5C shows the time-dependent photocatalytic conversion of  $\text{CO}_2$  into hydrocarbons over  $\text{NH}_2$ -CNPs. It can be seen that the yield of  $\text{CH}_3\text{OH}$  is significantly higher than that of  $\text{CH}_4$ ,  $\text{H}_2$ ,  $\text{C}_2\text{H}_5\text{OH}$  and CO. In addition, the amount of the photocatalytic product was substantially unchanged after 10 hours of reaction, indicating that  $\text{NH}_2$ -CNPs have a faster photocatalytic reaction rate. After the 10 hours of reaction, the total amount of products was 807.56  $\mu\text{mol g}^{-1}$  cat, and the amount of  $\text{CH}_3\text{OH}$  was 618.7  $\mu\text{mol g}^{-1}$  cat. Therefore, the calculated selectivity for the conversion of  $\text{CO}_2$  to  $\text{CH}_3\text{OH}$  was 76.6%. The inset of Fig. 5C shows the change in  $\text{CH}_3\text{OH}$  yield produced by photocatalytic  $\text{CO}_2$  reduction using  $\text{NH}_2$ -CNPs after three cycles. In each cycle, the reaction liquid was changed, and the illumination time was 6 h. The results show that after reusing 3 times,  $\text{NH}_2$ -CNPs gave a stable performance with repeatable  $\text{CH}_3\text{OH}$  production. The  $\text{CH}_3\text{OH}$  yield in the third cycle was 89.4% of the yield in the first cycle. This suggests that the  $\text{NH}_2$ -CNPs are suitable for photocatalytic  $\text{CO}_2$  reduction. We also examined the non-aminated CNPs photocatalytic  $\text{CO}_2$  reduction products. It was found that the  $\text{CH}_3\text{OH}$  yield in the liquid products was only 91.70  $\mu\text{mol g}^{-1}$  cat, about 1/6th of the  $\text{CH}_3\text{OH}$  yield when using the  $\text{NH}_2$ -CNPs photocatalyst.

To prove that the catalyst, illumination, and  $\text{CO}_2$  are the necessary requirements for photocatalytic  $\text{CO}_2$  reduction to  $\text{CH}_3\text{OH}$ ,  $\text{CH}_4$ ,  $\text{H}_2$ ,  $\text{C}_2\text{H}_5\text{OH}$  and CO, we conducted three control experiments under non-catalyst, non-illumination, and non- $\text{CO}_2$  conditions. The experiments were performed according to Section 2.5, with illumination time (if any) of 6 h. No products were detected.

### 3.3 $\text{CO}_2$ photocatalytic reduction mechanism for $\text{NH}_2$ -CNPs

To reveal that the  $\text{NH}_2$ -CNPs have greater photocatalytic reduction of  $\text{CO}_2$  activity than CNPs, we first analyzed the type of basic sites and their distribution on the catalyst surface by  $\text{CO}_2$ -TPD. The results are shown in Fig. 6A. Generally, the area of the desorption peak reflects the number of active sites on the catalyst surface, while the temperature of the desorption peak reflects the adsorption intensity of the corresponding species at active sites.<sup>38</sup>  $\text{NH}_2$ -CNPs exhibited a weak  $\alpha$  peak in the low-temperature zone (162 °C), which is generally considered as the  $\text{CO}_2$  physical adsorption peak of the catalyst. At around

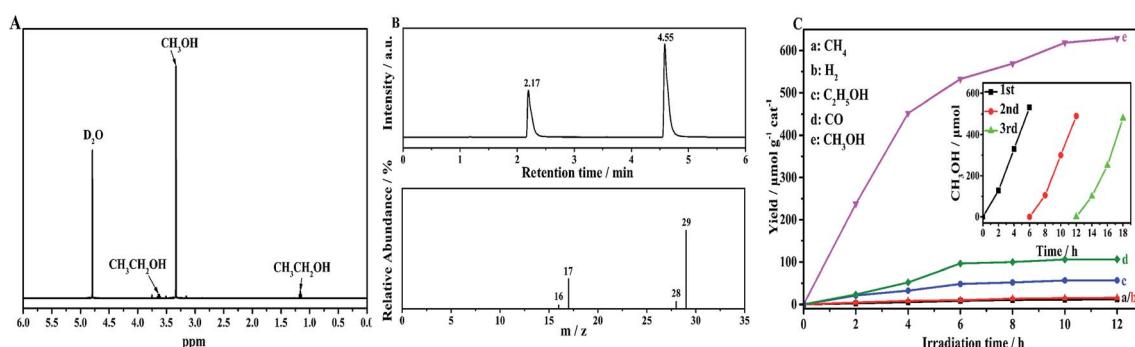

Fig. 5 (A) <sup>1</sup>H NMR spectra of the aqueous samples after 6 h of irradiation. (B) GC-MS spectral ( $m/z = 16, 17, 28, 29$ ) analyses of the carbon source for the evolved  $\text{CH}_4$  and CO in the photocatalytic conversion of <sup>13</sup>CO<sub>2</sub> on  $\text{NH}_2$ -CNPs. (C) Time-dependent photocatalytic conversion of  $\text{CO}_2$  into hydrocarbons over  $\text{NH}_2$ -CNPs (the inset shows the long-term time curve for the recovered  $\text{NH}_2$ -CNPs from the photocatalytic  $\text{CO}_2$  synthesis of  $\text{CH}_3\text{OH}$ , with replacement of the solution and photocatalyst (recovered) every 6 h).

Fig. 6 (A) The CO<sub>2</sub>-TPD profiles of the CNPs (a) and NH<sub>2</sub>-CNPs (b). (B) DR UV-vis spectra of the CNPs (a) and NH<sub>2</sub>-CNPs (b). (C) The calculation of the band gap of the CNPs (a) and NH<sub>2</sub>-CNPs (b) based on the (Ahv)<sup>2</sup> versus  $h\nu$  curve.

350 °C, the CO<sub>2</sub>-TPD spectra of both CNPs and NH<sub>2</sub>-CNPs showed a strong β peak, corresponding to a medium-strong adsorption of catalyst, indicating that both CNPs and NH<sub>2</sub>-CNPs have CO<sub>2</sub> adsorption. NH<sub>2</sub>-CNPs demonstrated a broad γ peak at 460 °C, suggesting strong CO<sub>2</sub> adsorption sites in NH<sub>2</sub>-CNPs. In addition, the adsorption peak area of NH<sub>2</sub>-CNPs is apparently larger than CNPs. Based on the above results, it can be concluded that NH<sub>2</sub>-CNPs have improved basic site types and distribution compared to CNPs. This is an important reason why NH<sub>2</sub>-CNPs have higher activity than CNPs in CO<sub>2</sub> photocatalytic reduction.

The photocatalytic process often involves the light excitation of the catalyst, photocarrier separation, migration, and recombination, as well as the generation of active species and the subsequent oxidation and reduction reactions. Among them, the absorption range and intensity are two important factors affecting the CO<sub>2</sub> photocatalytic reduction performance. Fig. 6B shows the measured UV-vis spectra of CNPs and NH<sub>2</sub>-CNPs. According to the figure, both materials can absorb visible light, while NH<sub>2</sub>-CNPs have a broader absorption range and intensity than CNPs. Thus, after being aminated, the CNPs' response to visible light is enhanced. In this work, we employed excitation light with a wavelength greater than 420 nm for the photocatalytic reaction. The highest photon energy was 2.95 eV. The incident photon energy must be equal to or greater than the material band gap to excite electrons from the VB to CB and generate holes in the VB for the subsequent redox reaction.<sup>39</sup> Thus, to prove that the CNPs and NH<sub>2</sub>-CNPs can be excited by visible light, we measured their DR UV-vis curves, and used eqn (1) to calculate and plot the relationship between (Ahv)<sup>2</sup> and  $h\nu$ .<sup>40</sup> By extending the straight-line portion of the curve to the x-axis, the energy band gaps (E<sub>g</sub>) of CNPs and NH<sub>2</sub>-CNPs were obtained, which were 2.42 and 2.02 eV, respectively (Fig. 6C). This further suggests that NH<sub>2</sub>-CNPs have stronger visible light absorption than CNPs to generate electrons and holes. This is another important reason why NH<sub>2</sub>-CNPs have higher activity than CNPs in CO<sub>2</sub> photocatalytic reduction.

$$A = \frac{K(h\nu - E_g)^{\frac{1}{2}}}{h\nu} \quad (1)$$

where A is the absorption coefficient, K is a constant, and E<sub>g</sub> is the energy band gap.

After the catalyst is excited by light, the photogenerated electrons and holes have two pathways: (i) migrating to the surface of the catalyst and triggering the subsequent photocatalytic reduction reaction; (ii) recombining with each other. Apparently, to enhance the photogenerated electron–hole pair separation efficiency, the catalyst surface must have clear pathways for electrons. It is generally considered that the semi-circle in the EIS curve represents the transfer resistance for electrons in the pores of the composite material. Semi-circles with larger diameters correspond to poorer electron transfer capability. Thus, to investigate the separation efficiency of photogenerated electron–hole pairs, we measured the EIS curves for CNPs and NH<sub>2</sub>-CNPs under the open circuit potential; the results are shown in Fig. 7A. According to the Nyquist curve, after the CNPs are aminated, the impedance of NH<sub>2</sub>-CNPs is significantly lower compared to the CNPs. This is likely due to the defects in NH<sub>2</sub>-CNPs, which can trap more photogenerated electrons *via* the quantum confinement effect, enhancing the separation efficiency of electron–hole pairs in the composite catalyst, leading to lower sample impedance.

The transient photocurrent–time curve is an effective way to study the transfer of photogenerated carriers on the surface of the catalyst. Fig. 7B shows the photocurrent–time curve of CNPs and NH<sub>2</sub>-CNPs electrodes in a 0.5 M Na<sub>2</sub>SO<sub>4</sub> solution with illumination by a xenon lamp ( $\lambda > 420$  nm) under open circuit potential and at room temperature. There are three differences between the transient photocurrent–time curves of CNPs and NH<sub>2</sub>-CNPs: (i) NH<sub>2</sub>-CNPs have larger steady-state photocurrent density than CNPs. This suggests that NH<sub>2</sub>-CNPs can excite more photogenerated electrons for photocurrent compared to CNPs. (ii) Upon turning on the light, the photocurrent of CNPs increases quickly, while the photocurrent of NH<sub>2</sub>-CNPs increases slowly. This is because upon illumination, CNPs can be quickly excited and generate electrons, while part of the carriers in NH<sub>2</sub>-CNPs are trapped and cannot transfer in time, leading to a slow increase to the maximum.<sup>41</sup> (iii) Upon cutting-off the light, the photocurrent of CNPs quickly drops to zero, while the photocurrent of NH<sub>2</sub>-CNPs decreases exponentially to a “tail” rather than zero. This is because the previously trapped charges are gradually released, generating low current and slowing down the decrease of the photocurrent to a non-zero value.<sup>42</sup> Based on the transient photocurrent–time curve, it can be concluded that NH<sub>2</sub>-CNPs can generate more

Fig. 7 (A) Nyquist plots of the CNPs (a) and  $\text{NH}_2$ -CNPs (b). (B) The transient photocurrent responses of the CNPs (a) and  $\text{NH}_2$ -CNPs (b) in 0.5 M  $\text{Na}_2\text{SO}_4$  aqueous solution under visible-light ( $\lambda > 420 \text{ nm}$ ) irradiation.

photocarriers, and due to surface defects, the photo-generated carriers can be effectively separated. Even after the light is turned off,  $\text{NH}_2$ -CNPs can still release a small amount of charges for photocatalytic  $\text{CO}_2$  reduction. This is another reason that  $\text{NH}_2$ -CNPs have better photocatalytic performance.

Based on the above analysis, we concluded that the mechanism of photocatalytic  $\text{CO}_2/\text{H}_2\text{O}$  reduction by  $\text{NH}_2$ -CNPs is as shown in Fig. 8. The analysis of UV-vis DRS and band gap curves revealed that the band gap of  $\text{NH}_2$ -CNPs decreased from 2.42 eV for CNPs to 2.02 eV, indicating that the  $\text{NH}_2$ -CNPs have enhanced response to visible light and can generate more electrons and holes (eqn (2)). The PL, EIS, and  $I-T$  results show that the photogenerated electron–hole pairs in  $\text{NH}_2$ -CNPs can be easily separated, and the electrons can be transferred to the surface of the catalyst for the  $\text{CO}_2$  reduction reaction (eqn (3)–(8)). The reduction potential of  $\text{NH}_2$ -CNPs and the generated electron quantities are likely to be the same as the reduction potential for  $\text{CH}_3\text{OH}$  production and the required electron amount, respectively. Therefore, the primary product of photocatalytic  $\text{CO}_2$  reduction by  $\text{NH}_2$ -CNPs is  $\text{CH}_3\text{OH}$ .

Fig. 8 Schematic of the mechanism of the photocatalytic  $\text{CO}_2$  reduction with water on  $\text{NH}_2$ -CNPs.

## 4. Conclusions

Using  $\text{HNO}_3$  pre-treated coal samples from Wucaiwang, Xinjiang, China, nano-scale crystalline carbon was fabricated from coal by the hydrogen peroxide oxidation method. After being linked with oxygen-containing groups such as hydroxyl, the coal-based CNPs with  $\text{sp}^2$  carbon architecture and multilayer graphene fragmentation structure were obtained. Next, sulfonyl chloride chlorination and ethylenediamine passivation were adopted to dope the CNPs with nitrogen and sulfur and produce aminated coal-based carbon nanoparticles ( $\text{NH}_2$ -CNPs) for photocatalytic  $\text{CO}_2$  reduction. The results show that  $\text{NH}_2$ -CNPs possess enhanced visible light response, leading to more photo-generated electrons that contribute to the photocurrent. Moreover, since the surface of  $\text{NH}_2$ -CNPs has a defect structure, the photogenerated carriers can be effectively separated. Even upon turning off the illumination, the  $\text{NH}_2$ -CNPs can still release a small amount of charge for photocatalytic  $\text{CO}_2$  reduction, improving the overall catalytic performance. This work contributes to better controlling the optoelectronic properties of carbon nanomaterials, and provides a new approach to further utilize coal resources for high-performance materials.
