Electro-oxidation of amino-functionalized multiwalled carbon nanotubes†

Yuanyuan Lu,^a Xiuting Li^b and Richard G. Compton^{*,a}

We report the electrochemistry of amino-functionalized multiwalled carbon nanotubes (MWCNTs-NH₂) in the pH range from 0.3 to 6.4 using quantitative cyclic voltammetry (CV) and single entity electrochemistry measurements, making comparison with non-functionalized MWCNTs. CV showed the latter to both catalyze the solvent (water) decomposition and to undergo irreversible electro-oxidation forming oxygen containing surface functionality. The MWCNTs-NH₂ additionally undergo an irreversible oxidation to an extent which is dependent on the pH of the solution, reflecting the variable amount of deprotonated amino groups present as a function of pH. Nano-impact experiments conducted at the single particle level confirmed the oxidation of both types of MWCNTs, showing agreement with the CV. The pK_a of the amino groups in MWCNTs was determined *via* both electrochemical methods giving consistent values of ca. 2.5.

Introduction

The exceptional physical properties,¹ including excellent electrical conductivity,² high porosity³ and specific surface area,⁴ of multiwall carbon nanotubes (MWCNTs) have led to their widespread use for example in nanodevices like transistors⁵ and nanosensors,^{6,7} for composite reinforcement,⁸ in metal (ion) nanocomposites⁹ and especially as catalyst supports in both chemical and electrochemical reactions.¹⁰ However, the application of pure MWCNTs is limited especially in detection devices such as electrochemical detectors and biosensors with immobilized biomolecules due to their hydrophobic nature and low dispersibility.¹¹ That said, functional groups, notably

-COOH, -OH and -NH₂, either generated on or covalently attached to the carbon surface¹² usefully confer a more hydrophilic character allowing much better compatibility with certain solvents, especially water.^{13,14}

Amino-functionalized MWCNTs (MWCNTs-NH₂) have aroused considerable interest since the amino groups attached to the CNTs allows a diversity of further chemical functionalization as well as showing valuable properties in themselves¹⁵ notably as absorbents for metal ions,^{16,17} acting as supports for the preparation of electrocatalysts^{18,19} and facilitating the fabrication of (bio) sensors.^{20,21} The formation of MWCNTs-NH₂ have been realized by different approaches. Generally the first step is the oxidation of MWCNTs by treatment with concentrated acids (sulfuric acid or nitric acid) or other oxidative protocols to generate carboxylated MWCNTs (MWCNT-COOH).^{21,22} These oxidized CNTs are subsequently linked to amines to form various amides or esters through different chemical reactions for example with ethylenediamine¹⁶ or diethylenetriamine.²³ Finally, decarbonylation is performed to remove the other carbonyl group linked between the MWCNT and the N atom in the amide so creating amino groups attached directly to carbon atoms in the CNT.

The amino groups in MWCNTs-NH₂ are basic and become protonated in acidic solution. Thus, the acid-base characteristics of the -NH₂/-NH₃⁺ pair underpins all MWCNTs-NH₂ chemistry in aqueous solution. In this report, we focus first on the electrochemistry of MWCNTs-NH₂ comparing it with that of MWCNTs and second on measuring the acid dissociation constant (pK_a) of the amino groups bonded to single, isolated MWCNTs and in ensembles of the latter. We note that in principle, the pK_a of functional groups attached to the surface of CNTs may differ very significantly from the pK_a of the same

groups in small molecules in solution, since the hydrophobic/hydrophilic nature of the CNT surface may markedly influence the thermodynamics of the acid–base reaction, for example by altering the local water structure. Quantitative information about these differences is rather limited but, for instance, the pK_a of formic acid is 3.7 (ref. 24) at 298 K whilst the corresponding pK_a for the carboxylic acid group within MWCNTs has been measured to range from 3.6 (ref. 25) to 6.3 (ref. 26) according to the extent of oxidation of the surface. Similar effects have been noted for carboxylic acid groups on glassy carbon surfaces,²⁷ while the pK_a of water, alcohols and phenols are 15.7 (ref. 28), 15.9 (ref. 29) and 9.9 (ref. 30) respectively compared to hydroxyl group on the functionalized MWCNTs with a pK_a estimated to be below 10.0.²⁶

Knowledge of the pK_a of MWCNTs-NH₂ is essential in their utilization most notably in terms of controlling the uptake of metal ions and in exploiting the chemical reactivity of the amino-groups as well as being of fundamental. We note that significant difference between the pK_a values of amino groups in molecules and bound covalently to the surface of graphite has been noted by Abiman *et al.*³¹ In the work reported below, two electrochemical techniques are used to estimate the pK_a of MWCNTs-NH₂ so as to probe their acid/base behavior either as ensembles of many CNTs drop-casted on an electrode surface or as single CNTs in solution. The first method utilizes cyclic voltammetry (CV) at a glassy carbon macroelectrode (GCE) modified with MWCNTs-NH₂, and for comparison with MWCNTs, in a solution electrolyte at different pH values. Both types of nanotube are seen to catalyze the solvent decomposition and to undergo chemically irreversible surface modification leading to the introduction of oxygen functionality. In addition, the MWCNTs-NH₂ show additional current at suitably high pH due to oxidation of unprotonated -NH₂ groups. In contrast to the conventional voltammetric method for solution phase molecules, based on peak potential shifts upon addition of acid,³² the pK_a of the MWCNTs-NH₂ is obtained by estimating the amount of free -NH₂ groups on the surface *via* electro-oxidation on the assumption that the protonated amino groups are electro-inactive in contrast to the unprotonated groups. This allows the estimation of the pK_a of the CNTs in the drop-casted ensemble. The second method corresponds to a nano-impact experiment of single MWCNTs-NH₂ particles using a carbon microelectrode in the electrolyte solution containing a suspension of MWCNTs-NH₂. In the nano-impact experiment, the random collisions of the particles in the suspension with the electrode held at a suitable potential allows electrochemical reactions to occur for the duration of the impact whilst the particle is in electrical contact with the electrode. Current–time traces ('chronoamperometry') are recorded as a function of the potential and impacts are revealed by the appearance of spikes and steps on the current.^{33–35} Both MWCNTs and MWCNTs-NH₂ show impact signals consistent with the voltammetry and, in the case of the impact spikes, additional charge assigned to oxidation of unprotonated -NH₂ groups which was measured as a function of the solution pH. In this way, the integrated current–time spikes give the charge partly associated with the oxidation of the -NH₂ groups and hence the amount of free -NH₂ groups present as a function of pH. Thus,

a larger charge is seen for higher pH (>4) where the groups are essentially all unprotonated, whilst for pH < 2 a smaller but not negligible current is seen since the electro-inactive -NH₃⁺ groups dominate to reduce the magnitude of the current; the origin of the remaining current is explored by comparison with analogous measurements on MWCNTs which do not contain amino groups. In this way, the pK_a of single MWCNTs-NH₂ can be found and compared with the value obtained for ensembles *via* cyclic voltammetry. The origin of the smaller current spikes seen on the non-functionalized MWCNTs and the steps on both types of CNTs are attributed in part to the oxidation of the carbon tubes themselves with the formation of quinone groups and other oxygen functionality as previously reported from cyclic voltammetry measurements allied to spectroscopic analysis^{36,37} in addition to enhanced (catalyzed) solvent decomposition. Here we report the first application of single entity electrochemistry (aka 'nano-impacts') to the electro-oxidation of single MWCNTs.

Results and discussion

This section reports the electro-oxidation of MWCNTs and MWCNTs-NH₂ using both cyclic voltammetry and nano-impact experiments in the pH range of 0.3 to 6.4. The oxidative peak currents seen in cyclic voltammetry of MWCNTs and MWCNTs-NH₂ modified GCEs are compared with the average charge of the current spikes and/or steps seen in nano impact experiments from MWCNTs and MWCNTs-NH₂ particles, allowing the contributions from the electro-oxidation of the CNTs to be distinguished from the oxidation of the amino groups, if present. The pH dependency of the latter is used to infer the pK_a of the amino groups. First the electro-oxidation of MWCNTs ensembles without functionalization are investigated using cyclic voltammetry. Then to further confirm the oxidation process, MWCNT particle impact experiments are conducted.

Cyclic voltammetry (CV) of MWCNTs

To investigate the electrochemical oxidation of MWCNTs, cyclic voltammograms at bare and MWCNTs modified GCEs were first recorded in 0.1 M KNO₃ (pH adjusted to 6.4) in the potential range from 0.1 V to 2.0 V *vs.* SCE at a scan rate of 50 mV s⁻¹. As depicted in Fig. 1(A), there is a single chemically irreversible oxidation peak observed at 1.68 V for the MWCNTs modified GCE. The magnitude of the peak current increased linearly with the amount of MWCNTs dropcast (Fig. 1(B)) and was assigned in part (see below) to the electro-oxidation of the MWCNTs based on its FTIR characterization indicating the existence of -OH group bonded to MWCNTs (Fig. S1†) and previous reports.^{38,39} Notably, previous work using CV and X-ray Photoelectron Spectroscopy (XPS) analysis^{36,37} has associated the electrochemical oxidation of MWCNTs with increased oxygen content and assigned the oxidative peak to the formation of quinoidal and ketone functional groups at the surface of carbon nanotubes. The formation of functional groups after electrochemical oxidation of the MWCNTs is also evident on the basis of voltammetry. Fig. 1(C) shows the cyclic voltammograms of MWCNTs modified GCE in 0.1 M KNO₃ (pH = 6.4) in which

Fig. 1 (A) Cyclic voltammograms of a bare GC electrode (black dashed curve) and a MWCNTs modified GCE (blue solid curve) immersed in 0.1 M KNO_3 solution ($\text{pH} = 6.4$) by sweeping the potential from 0.1 V to 2.0 V vs. SCE; (B) voltammograms of MWCNTs modified GCEs with different modification amount of 0.05, 0.1, 0.2, 0.4 and 0.8 μg MWCNTs following background correction to the original cyclic voltammogram scanned in 0.1 M KNO_3 ($\text{pH} = 6.4$) (inlay: plot of oxidative peak current versus MWCNTs modification amount on the polished GCE); (C) cyclic voltammograms of MWCNTs modified GCE recorded with a sweep from +1.0 V to -1.5 V after previous scan from 0.10 V to 1.78 V interrupted at a potential of 1.78 V for different durations of 0 s–200 s in 0.1 M KNO_3 ($\text{pH} = 6.4$) (inlay: the cyclic voltammograms scanned across the full range from 1.78 V to -1.50 V when the duration of the fixed potential oxidation was 200 s) (D) Cyclic voltammograms of a MWCNTs modified GCE immersed in 0.1 M HNO_3 ($\text{pH} = 1.0$) and 0.1 M KNO_3 solutions at different pH values of 2.5, 3.5, 4.0 and 6.4 (inlay: pH variable study of oxidative peak current obtained from MWCNTs modified GCEs using CV after background subtraction as described in Experimental section). All voltammograms were conducted at a scan rate of 50 mV s^{-1} .

a potential scan from 1.0 V to -1.5 V with a return scan to 1.0 V is held for different times (0, 50, 100, 200 seconds) at +1.78 V in the middle of the scan, corresponding to a potential after the oxidative peak attributed to the immobilized CNTs. Two reduction peaks (c_1 and c_2) appeared at -0.34 ± 0.14 V and -0.75 ± 0.16 V which increased in size in proportion to the length of time held at +1.78 V. The voltammetric reduction peaks c_1 and c_2 are similar to the behavior observed from the quinone/hydroquinone system in acid solution.⁴⁰ The requirement however to hold the potential at an oxidizing value for a period of up to 200 seconds in order to see a voltammetric signal suggests that the formation of oxygenated species is not the dominant process in the CV peak. Rather it is likely that the peak represents a catalysis by the CNTs of the solvent oxidation possibly further catalyzed by the simultaneously introduced oxygen functionality. This is consistent with the enhanced currents in the second anodic scans shown in Fig. 1(C). However, we return to this issue below after nano impact measurements are reported.

The pH variation of the oxidative peak at MWCNTs modified GCEs was studied by recording CVs in the pH range 1.0 to 6.4 (Fig. 1(D)) as described in the Experimental section. The

potential of the oxidative peak was pH independent with an average value of 1.71 ± 0.03 V. The peak current data obtained in MWCNTs modified GCEs after background subtraction were plotted against the corresponding solution pH value (inlay of Fig. 1(D)) again indicating independence of the electro-oxidation of MWCNTs on pH in the range studied. This suggests that the rate limiting step for the oxidation of the CNTs leading to the introduction of oxygen functionality is slow electron transfer prior to any proton release.

Electro-oxidation of MWCNTs: nano-impact experiments

Nano impact experiments were conducted to probe the electro-oxidation of MWCNTs *via* the collision of individual MWCNTs particles with a microelectrode held at different potentials. A freshly polished carbon micro-disc electrode (diameter 33 μm) was first inserted into a suspension of 0.01 g L^{-1} MWCNTs supported by 0.1 M KNO_3 with a pH of 6.4, as described in the experimental section and separately for comparison into a blank solution without particles. As seen in Fig. 2(A), at an applied potential of 1.90 V vs. SCE, clear current steps and spikes were seen in the presence of MWCNTs (black line)

Fig. 2 (A) Chronoamperograms of a carbon micro-disc electrode ($d = 33 \mu\text{m}$) immersed in a 0.1 M KNO_3 ($\text{pH} = 6.4$) solution containing 0.01 g L^{-1} MWCNTs (black line) or not (red line) at a potential of 1.90 V vs. SCE. The inset is an enlarged view of impact spike and step at 1.90 V ; overlay of the plot of average impact spike charge (B) and step charge (C) as a function of applied potentials with the cyclic voltammogram (black line) of MWCNTs modified GCE; (D) average step currents observed as a function of applied potential in 0.1 M KNO_3 ($\text{pH} = 6.4$) containing 0.01 g L^{-1} MWCNTs (the error bars are derived from $\text{SD}/(n)^{1/2}$, where SD is the standard deviation and n is the number of the spikes or steps).

whereas no spikes or steps were observed in the absence of MWCNTs (red line). The average spike height (current) at 1.90 V was calculated to be $0.64 \pm 0.06 \text{ nA}$ and the average step height (current) at 1.90 V were measured as $0.25 \pm 0.04 \text{ nA}$. Based on the frequency of spikes and steps in each chronoamperogram curve, the appearance ratio of spikes to steps is calculated to be 1.8 ± 0.7 .

Further, impacts for the electro-oxidation of MWCNTs were observed at various potentials from 1.4 V to 2.0 V vs. SCE in the same solution. It was found that clear current spikes were observed in the chronoamperograms upon particle collisions with the electrode held at oxidizing potentials ($1.7\text{--}2.0 \text{ V}$) and the current steps were observed in the chronoamperograms upon particle collisions with the electrode held at oxidizing potentials ($1.6\text{--}2.0 \text{ V}$) (Fig. 3(A)–(D)). The rise times of the steps at high potentials may in part be controlled by the charging of the double layer associated with the CNTs. At and below 1.50 V , no impact signals were detected (see Fig. S2†). It is speculated that the steps are primarily associated with CNT catalysis of the solvent decomposition leading to the sustained currents seen for the impact duration. On the basis of the cyclic voltammetry reported above these will also be associated, to a smaller extent, by the oxidation of the nanotubes themselves forming surface functionality such as quinones. These may further enhance the catalysis of the solvent decomposition⁴¹ corresponding to the oxidation of water to oxygen. The mean impact frequencies and

duration of impact signals as a function of potential are plotted in Fig. S3(A) and S3(B)† respectively, the frequency of spikes and steps were found to only slightly increase while each average duration stayed nearly the same from which over the potential range of 1.7 to 2.0 V . The step features require a sustained electrical contact between the tube and the electrode of average duration $4.6 \pm 0.9 \text{ s}$ (43 measurements). In contrast the spike features require a much shorter contact time (of average length $12 \pm 1 \text{ ms}$ from 53 measurements) and may reflect simply the end of a tube contacting the electrode. In this case, given the known greater susceptibility of tube ends to electrochemical reaction,^{42,43} these may be associated with the oxidation of the CNTs to oxygenated functionality. Fig. 4 shows a schematic view of the possible different collisions associated with the spikes and steps.

The average charges of the individual spikes and steps from the collision of MWCNTs were measured as a function of the applied potential and the results are shown in Fig. 2(B) and (C) where the turn on of the electro-oxidation is seen to be consistent with cyclic voltammogram of MWCNTs modified GCEs in the same solution. A plateau of *ca.* 0.41 pC per spike was seen when the potential exceeded 1.90 V , but no spikes were observed at the potential more negative than 1.70 V , indicating that those spikes are a result of MWCNTs oxidation. The same condition occurred in the steps when the potential was more positive than 1.60 V , the average charge was seen to increase

Fig. 3 (A)–(D) Examples of representative chronoamperometric profiles of nano-impact at different potentials (1.60, 1.70, 1.80 and 2.00) in a 0.1 M KNO_3 ($\text{pH} = 6.4$) solution containing 0.01 g L^{-1} MWCNTs. No spikes or steps were detected below/at 1.50 V.

Fig. 4 A schematic view of the possible different collisions of a single MWCNT on the micro-disc electrode ($d = 33 \mu\text{m}$) associated with the spikes and steps.

gradually and reached a constant level around *ca.* 0.50 nC but no steps were observed at the potential more negative than 1.60 V. The small difference in onset potentials might be speculated to indicate a different extent of the solvent oxidation

as compared to oxidation of the CNT. The average impact step current plotted against the applied potential (Fig. 2(D)) indicated an upward trend over a potential range from 1.60 V consistent with the predominant process being water oxidation.

The insensitivity of the impacts (spikes and steps) to pH was demonstrated *via* an experiment carried out at a potential of 1.90 V in 0.1 M HNO_3 ($\text{pH} = 1.0$) containing 0.01 g L^{-1} MWCNTs suspension. Concerning the spikes, these had an average charge of $0.40 \pm 0.03 \text{ pC}$ as measured from 48 current spikes consistent with the average charge from the oxidative spikes obtained in 0.1 M KNO_3 at $\text{pH} = 6.4$ as reported above $0.43 \pm 0.05 \text{ pC}$ (the charge distribution is seen in Fig. S4(A) and S4(B)† respectively). The oxidative impact responses of MWCNTs particle have an average frequency of $0.053 \pm 0.019 \text{ s}^{-1}$, consistent with the $0.051 \pm 0.012 \text{ s}^{-1}$ frequency of the spikes observed in chronoamperograms in 0.01 g L^{-1} MWCNTs + 0.1 M KNO_3 ($\text{pH} = 6.4$).

As for the steps appeared in 0.1 M HNO_3 ($\text{pH} = 1.0$) in the presence of MWCNTs, an average charge of $0.47 \pm 0.05 \text{ nC}$ as measured from 52 current steps. Compared with the average charge from the oxidative steps obtained in 0.1 M KNO_3 at $\text{pH} = 6.4$ ($0.48 \pm 0.07 \text{ nC}$) (the charge distribution is seen in Fig. 4(C) and S4(D)† respectively). The oxidative impact responses of MWCNTs particle have an average frequency of $0.044 \pm 0.008 \text{ s}^{-1}$, consistent with the $0.040 \pm 0.007 \text{ s}^{-1}$ frequency of the steps observed in chronoamperograms in 0.01 g L^{-1} MWCNTs + 0.1 M KNO_3 ($\text{pH} = 6.4$). The result from the single electrochemistry of MWCNTs again indicates that the electro-oxidation reaction extent of pure MWCNTs is not controlled by solution pH.

The much larger charges resulting from the sustained currents seen in the steps are consistent with the assignment of these features to CNT catalyzed solvent decomposition. Moreover, the charges passed in the impact steps (0.48 ± 0.07 nC) are comparable in magnitude to those seen in the cyclic voltammetry when measured on a per nanotube basis (0.46 nC, see ESI Section 5† for details). This suggests that the peak seen in the cyclic voltammogram is not due to the formation of a finite number of oxygenated functionality, as also suggested by the relative size of the reductive CV features discussed above, but rather might be attributed to the porous nature of the CNT layer on the electrode surface (\sim at least 13 layers, see ESI Section 6†) which can trap the protons released in the oxidation of the water leading to a local build-up of acidity. However, the above data indicates that the currents resulting from CNT catalysis of the solvent oxidation are insensitive to the value of the pH and hence the inhibition of the CNT catalyzed solvent decomposition resulting in a voltammetric peak may result from excessive electro-oxidation of the CNTs, consistent with the data in Fig. 1(C) showing not only progressively increasing oxygen functionality resulting from sustained electro-oxidation but also a change in the reductive voltammetric signal.

We next consider the origin of the spike currents where the charge is passed for *ca.* 12 ± 1 ms before terminating. These may reflect different types of CNT-electrode collision than occur during the step features. Since the latter persist with a steady current for tens of seconds, we suggest that the steps require electrical contact between the micro-disc electrode and CNT *via* the sides of the tubes, see Fig. 4. The spikes may reflect electrical contacts between the tube ends and the electrodes with the short, finite duration controlled either by the nature of the collision or, possibly, by the formation of insulating functionality *via* oxidation of the tube ends. The latter possibility is discounted by the calculation (see ESI Section 7†) that the average charge per spike results in rather more functional groups than could be accommodated at the end of a nanotube.

Cyclic voltammetry (CV) of MWCNTs-NH₂

Next the electrochemical behavior of MWCNTs-NH₂ was explored by applying cyclic voltammetry first in 0.1 M KNO₃ (pH = 6.4) at a scan rate of 50 mV s⁻¹. The potential range was chosen to be from 0.1 V to 2.0 V as shown in Fig. 5(A). In comparison with the MWCNTs modified GCE, a larger oxidative peak appeared with a peak potential of *ca.* 1.72 V vs. SCE under

Fig. 5 (A) Cyclic voltammograms of MWCNTs modified GCE (blue curve) and MWCNTs-NH₂ modified GCE (red curve) immersed in 0.1 M KNO₃ solution (pH = 6.4); (B) voltammograms of MWCNTs-NH₂ modified GCEs with different modification amount of 0.05 , 0.1 , 0.2 , 0.4 and 0.8 μ g MWCNTs-NH₂ following background correction to the original cyclic voltammogram scanned in 0.1 M KNO₃ (pH = 6.4) (inlay: plot of oxidative peak current versus MWCNTs-NH₂ modification amount on the polished GCE); (C) cyclic voltammograms of MWCNTs-NH₂ modified GCE recorded at $+1.0$ V to -1.5 V after previous scan from 0.10 V to 1.78 V with a hold at a potential of 1.78 V for different duration of 0 s– 200 s in 0.1 M KNO₃ (pH = 6.4) (inlay: the cyclic voltammograms scanned across the full range from 1.78 V to -1.50 V when the held time was 200 s); (D) cyclic voltammograms of MWCNTs-NH₂ modified GCE immersed in 0.1 M HNO₃ (pH = 0.3), 0.1 M HNO₃ (pH = 1.0) and 0.1 M KNO₃ solutions at different pH of 2.0 , 2.5 , 3.0 , 3.5 , 4.0 , 5.0 and 6.4 . All the voltammetry were conducted by using sweep potential from 0.10 V to 2.0 V vs. SCE at a scan rate of 50 mV s⁻¹ (inlay: pH variable study of oxidative peak current obtained from MWCNTs-NH₂ modified GCE using CV).

similar modification conditions. A good linear relationship between the height of the peak current and the amount of MWCNTs-NH₂ drop-cast was observed as shown in Fig. 5(B).

Analogous experiments to those conducted for MWCNTs were made to investigate the reductive voltammetric behavior following electro-oxidation of the MWCNTs-NH₂ at 1.78 V, focusing on the potential range from +1.0 V to -1.5 V. As seen in Fig. 5(C), two cathodic peaks appeared at -0.40 ± 0.05 V (c'_1) and -0.78 ± 0.14 V (c'_2) similar to what was seen in the cyclic voltammetric behavior of MWCNTs again suggesting that a small amount of the oxidative current is used to introduce oxygen containing functionality but that most of the current is CNT catalyzed solvent oxidation.

Cyclic voltammograms were recorded at different scan rates in the range of 25–400 mV s⁻¹ in 0.1 M HNO₃ (pH = 1.0) and 0.1 M KNO₃ (pH = 6.4). Polynomial fitting curves were used to infer the charge passed on a MWCNTs-NH₂ modified GCE as a function of scan rate (Fig. S6†). Extrapolation of the reciprocal charge against scan rate to zero scan rate gave the average charge of 6.0 mC in 0.1 M HNO₃ (pH = 1.0), which is approximately consistent with the charge passed at a MWCNTs modified GCE (7.0 mC) representing a similar extent of solvent oxidation and functional group formation in both types of CNT since the mass drop cast was the same in both cases and the individual tubes have similar surface areas (see Table 1). However, a clear difference was noticed for the average charge passed on a MWCNTs-NH₂ modified GCE in 0.1 M KNO₃ (pH = 6.4) which was markedly larger than that at pH 1 and calculated to be 9.5 mC, suggesting that the presence or not of deprotonated -NH₂ groups is greatly possible factor whereby the amine groups are deprotonated at high pH but protonated at pH 1 such that they are easily electro-oxidized at the higher pH but not at the lower pH.

To explore this possibility, the variation of the magnitude of the oxidative peak as a function of solution pH was measured in the range from 0.3 to 6.4. Fig. 5(D) shows an overlay of cyclic voltammograms for the oxidation of MWCNTs-NH₂ modified GCEs in various electrolytes: (a) 1.0 M HNO₃, (b) 0.1 M HNO₃ and (c) 0.1 M KNO₃ of different pH as controlled by small additions of 0.1 M HNO₃ or 0.5 M KOH assuming no ion pairing between nitrate and amino-groups on the CNTs.^{44–46} In this way the pH ranges from 0.3 to 6.4 was studied. The potential of the irreversible oxidative peak was unchanged with variation in pH with an average value of 1.73 ± 0.03 V. However, the plot of oxidative peak currents against pH value (inlay of Fig. 5(D)) shows an obvious pH-dependence in contrast to the MWCNTs modified GCEs. Specifically, the peak current was essentially pH independent between pH values of 0.3 to 2.5, then between pH 2.5 and 3.5, the height of oxidative peak current rose sharply as

the pH was increased. Finally at pH above 4.0, the oxidative peak current remained stable. Overall a characteristic sigmoid-like 'titration curve' curve was seen. The magnitude of the current seen in the lowest pH range is of the same order of magnitude to that recorded for unmodified MWCNTs (albeit of different radius and length to the MWCNTs), suggesting that the same electrocatalytic solvent oxidation reaction as noted above for MWCNTs is also seen in MWCNTs-NH₂ and occurs at essentially the same potential in both types of CNT. It is inferred that the oxidation potential of the unprotonated -NH₂ groups approximately coincides with that of the electro-oxidation of the solvent. It is worthwhile to mention that the rate limiting step for the solvent oxidation and amino groups on the MWCNTs are inferred in each case to be the electron transfer prior to any proton release as reflected in the independence of the corresponding oxidation potentials on pH.

The additional current observed at higher pH is attributed to the oxidation of unprotonated -NH₂ groups where further follow up chemistry is probable, on the basis of electro-oxidation mechanism of aromatic amines proposed by Weinberg,⁴⁷ considering that aromatic amines usually have analogous hexatomic ring structure as is present in CNTs and generically show a single oxidative peak at a potential above 1.0 V vs. SCE when oxidized at a carbon working electrode under acidic conditions.^{48,49} This possible mechanism also provides a reasonable explanation for the formation of the sigmoid-like 'titration' curve of oxidative peak height versus pH value. However, it is noted that the oxidation of the -NH₂ groups results in the release and build-up of protons so changing the local pH and extent of solvent oxidation. This precludes quantitative analysis of the CVs by subtraction of the 'blank' responses. Owing to the acid-base characteristics of the -NH₂/-NH₃⁺ pair, the electro-oxidation extent of electro-active -NH₂ decreases when the solution became more acidic as the generation of the protonated species.

Single particle electrochemistry of MWCNTs-NH₂

Analogous nano-impacts experiments of MWCNTs-NH₂ to those made for MWCNTs were conducted in 0.1 M KNO₃ (pH = 6.4) containing 0.01 g L⁻¹ MWCNTs-NH₂ at a freshly polished carbon micro-disc electrode. At a fixed potential of 1.90 V vs. SCE, clear impact signals (steps and spikes) as with MWCNTs were observed (Fig. 6).

Analysis of the step data showed that in terms of average current, duration and frequency, it was essentially indistinguishable from that recorded for MWCNTs using solutions of varying pH from 0.3 to 6.4 (representative chronoamperograms are shown in Fig. S7(A)–(E)†). The average step current seen only in the presence of MWCNTs-NH₂ fluctuated at 0.26 ± 0.06 nA which is close to the value (0.27 ± 0.04 nA) obtained from 0.1 M KNO₃ (pH = 6.4) containing MWCNTs and was pH independent (Fig. S7(F)†). The corresponding oxidative step frequency under different pH condition (Fig. S8(A)†) stay nearly constant with a mean value of 0.039 ± 0.005 s⁻¹, close to the frequency (0.037 ± 0.008 s⁻¹) of the steps observed in 0.1 M KNO₃ (pH = 6.4) containing 0.01 g L⁻¹ MWCNTs (albeit of different radius and

Table 1 The dimensions of MWCNTs and MWCNTs-NH₂

	MWCNTs	MWCNTs-NH ₂
Diameter	30 nm	15 nm
Length	20 μm	50 μm
External surface area	1.9×10^{-12} m ²	2.3×10^{-12} m ²

Fig. 6 Chronoamperograms of a carbon micro-disc electrode ($d = 33 \mu\text{m}$) immersed in a 0.1 M KNO_3 ($\text{pH} = 6.4$) solution containing MWCNTs-NH₂ (black line) or not (red line) at a potential of 1.90 V vs. SCE . The inset is an enlarged view of impact spike and step at 1.90 V in the presence of MWCNTs-NH₂.

length). The step duration was found to be steady at $4.8 \pm 1.0 \text{ s}$ (Fig. S8(B)†) again consistent with what is seen in the presence of non-functionalized MWCNTs ($4.7 \pm 0.9 \text{ s}$).

The spike data however showed interesting contrasts with those seen for MWCNTs. The average charge from 89 spikes (the charge distribution is shown in Fig. S9†) for MWCNTs-NH₂ at 1.90 V ($0.62 \pm 0.02 \text{ pC}$) was higher than the value ($0.43 \pm 0.05 \text{ pC}$) obtained from the collision of MWCNTs particle in 0.1 M KNO_3 ($\text{pH} = 6.4$), suggesting the oxidation of unprotonated -NH₂ groups bonded to MWCNTs.

To investigate the oxidative charge variation of MWCNTs-NH₂ as a function of pH, current-time transients were recorded in solutions varying pH from 0.3 to 6.4 (Fig. 7(A)). The average charges of the individual spikes from the collision of MWCNTs-

NH₂ were measured as a function of the pH and the results (Fig. 7(B)) show two plateaus one at high (>3.7) and the other at low (<1.8) pH, which agree well with the variation of the oxidative peak current against pH variation observed in CV and again can be attributed to the different extents of amino group oxidation reflecting whether the amine groups are protonated or not. The corresponding oxidative spike frequency under different pH condition (Fig. S8(A)†) stay nearly the same with a mean value of $0.048 \pm 0.010 \text{ s}^{-1}$, close to the frequency ($0.051 \pm 0.012 \text{ s}^{-1}$) of the spikes observed in 0.1 M KNO_3 ($\text{pH} = 6.4$) containing 0.01 g L^{-1} MWCNTs (albeit of different radius and length but similar area). While the spike duration was found to be unchanged at $15 \pm 2 \text{ ms}$ (Fig. S8(B)†) that is only slightly higher than that in the presence of non-functionalized MWCNTs ($12 \pm 1 \text{ ms}$). All the results evidenced that transient electrocatalysis of solvent oxidation and oxidation of the deprotonated amino groups on the MWCNTs jointly contributed to the electro-oxidative spikes see for MWCNTs-NH₂ but the latter resulted in a titration-like curve based on the experimental data from single and ensemble electrochemical behavior.

Determination of MWCNTs-NH₂ pK_a using cyclic voltammetry and nano impact data

The average pK_a of the amino groups in MWCNTs-NH₂ is defined by the equilibrium between protonated and unprotonated amino groups functionalized on the surface of carbon nanotubes:

$$\text{pH} = \text{pK}_a + \log_{10} \left[\frac{\text{MWCNTs-NH}_2}{\text{MWCNTs-NH}_3^+} \right] \quad (2)$$

In the following we estimate the pK_a from both the CV and impact data. First from the CV we assume that the difference in the peak current seen in acid (-NH₃⁺ only present) and in near neutral condition (-NH₂ exclusively present) reflects the extent of the deprotonation inferred in solution of higher pH. Thus,

Fig. 7 (A) Representative chronoamperograms of a carbon micro-disc electrode immersed in a 1.0 M ($\text{pH} = 0.3$) and 0.1 M HNO_3 ($\text{pH} = 1.0$) and 0.1 M KNO_3 solutions at different pH values of 1.8, 2.7, 4.1 and 5.3 containing 0.01 g L^{-1} MWCNTs-NH₂ at a potential of 1.90 V vs. SCE ; (B) the comparison of oxidative peak current from CV (black dots) and average charge from oxidative spikes (blue dots) as a function of solution pH.

Fig. 8 (A) Relationship between oxidative peak current of MWCNTs-NH₂ modified GCE and pH value of solution; (B) relationship between average charge of oxidative spikes and pH value of solutions in the presence MWCNTs-NH₂ (black square: experimental data; black solid line: simulated curve, and red dotted line: differential curve of experimental data).

the oxidative peak current (I_p) at a MWCNTs-NH₂ modified GCE reflects two parts: the deprotonated [MWCNTs-NH₂] and protonated [MWCNTs-NH₃⁺], then I_p can be described as:

$$I_p = I_{\text{NH}_2}[\text{MWCNTs-NH}_2] + I_{\text{NH}_3^+}[\text{MWCNTs-NH}_3^+] \quad (3)$$

Assuming the sum [MWCNTs-NH₂] + [MWCNTs-NH₃⁺] is a constant, according to eqn (1)–(3), the following equation can be obtained (4):

$$\text{p}K_a = \text{pH} - \log_{10} \left(\frac{I_{\text{NH}_3^+} - I_{\text{NH}_2}}{I_p - I_{\text{NH}_2}} - 1 \right) \quad (4)$$

where I_{NH_2} and $I_{\text{NH}_3^+}$ can be determined by the average values at high pH (>4) and low pH (<2). As shown in Fig. 8(A), the black solid line is the simulated curve using Origin Pro 2020 non-linear fitting function based on eqn (4) ($R^2 = 0.9942$), and $\text{p}K_a$ of MWCNTs-NH₂ was determined by the incremental ratio ($dI_p/d\text{pH}$) expressing the differential value from the simulated

curve data. The first derivative calculated for points could help to identify the equivalence point of the “titration” from its maximum value. Therefore, from the differential curves (Fig. 8(A) red dotted line), the $\text{p}K_a$ of MWCNTs-NH₂ was estimated to be 2.7 ± 0.1 based on the CV data.

For comparison, the $\text{p}K_a$ of amino group in MWCNTs was also estimated using the experimental data from nano impact. Using the same assumptions as above, a non-linear curve was fitted (see ESI Section 12[†]) to the average charge of oxidative spikes as a function of pH was plotted in Fig. 8(B) ($R^2 = 0.9656$, black solid line). The differential curve (red dotted line) reflected the change of incremental ratio ($dQ/d\text{pH}$) and the highest inflection point was estimated to be 2.3 ± 0.1 as the $\text{p}K_a$ of amino groups on the MWCNTs, which is slightly smaller than that inferred using the CV method. The breadth of the transition from low to high pH in Fig. 8(A) and (B) are similar and may reflect the response of amino groups in different locations on the tube surface.

Fig. 9 Schematic structure of the single layer of MWCNTs-NH₂.

Conclusions

The electro-oxidation of MWCNTs and MWCNTs-NH₂ have been studied by single and ensemble electrochemistry respectively within the range of pH values from 0.3 to 6.4. It opens up a new and generic approach to the study of the oxidation of entities made of carbon allotropes and of different forms of CNTs in particular. The MWCNTs-NH₂ and the MWCNTs at all pHs studied show catalysis of the solvent (water) decomposition together with the introduction of new surface functionality. The case of MWCNTs-NH₂ at higher pH shows excess oxidative charge in the case in impact spikes and peak current in the CV. The excess faradaic component is attributed to the electro-oxidation of the amino group when deprotonated, a process which is inhibited when they exist in the -NH₃⁺ form. Based on the pH variation of oxidative peak current in MWCNTs-NH₂ modified GCE and the oxidative spike average charge of one single MWCNTs-NH₂ particle, the $\text{p}K_a$ values of -NH₂ bonded to MWCNTs determined by two ways in our work are estimated to be around 2.5 at 298 K. This study will assist in controlling and rationalizing the chemical reactivity of the -NH₂ groups bonded to carbonaceous material utilized as a catalyst or support composites.

Experimental section

Chemicals and reagents

Amino multi-walled carbon nanotubes (MWCNTs-NH₂, amino ratio: ~0.45 wt%, outer diameter = 8–15 nm, inner diameter = 3–5 nm, length = 50 μm) were purchased from Nanjing XFNANO Materials Tech Co., Ltd (Nanjing, China). The MWCNTs-NH₂ were synthesized *via* the following procedure of three steps: (i) the introduction of carboxylic acid groups at defects (tube ends, vacancies, *etc.*) in the MWCNTs made by chemical vapor deposition (CVD) to form MWCNTs-COOH; (ii) the reaction of the -COOH groups to form -CO-NH₂ groups *via* chemical reaction with liquid ammonia;⁵⁰ (iii) decarbonylation to remove the carbonyl group, so that the amino groups become directly linked with carbon atoms in the MWCNTs to obtain the final product MWCNTs-NH₂, the structure is shown schematically in Fig. 9 with the NH₂ group attached to an aromatic ring.

Bamboo like multiwall carbon nanotubes (MWCNTs, BPD30L5-20, diameter = 30 ± 15 nm, length = 5–20 μm) were purchased from Nanolab (Brighton, MA, USA). The MWCNTs and MWCNTs-NH₂ were used for comparative experiments as described below. Their dimensions are compared in Table 1 and it is noticed that the external surface area of the two different types of individual carbon nanotubes are similar (~2 × 10⁻¹² m²) so permitting comparisons made below.

All chemicals were of analytical grade and were used as received without any further purification. Nitric acid (HNO₃, 70%), potassium hydroxide (KOH, 85%), potassium nitrate (KNO₃, 99.99%), ethanol (≥99.8% purity) were obtained from Sigma-Aldrich (Dorest, UK). 0.1 M KNO₃ with different pH values (adjusted by additions of 0.1 M HNO₃ or 0.5 M KOH) was used as a supporting electrolyte in all cyclic voltammetric and chronoamperometric measurements. All solutions were prepared in ultra-pure water at a resistivity of 18.2 MΩ cm at 298 K (Millipore, MA, USA) and were deaerated thoroughly with nitrogen (99.998%, BOC Gases plc) before use.

Cyclic voltammetry of MWCNTs and MWCNTs-NH₂ modified GCEs

A suspension of 0.1 g L⁻¹ MWCNTs-NH₂ was prepared by adding 1.0 mg of MWCNTs-NH₂ to 10 mL ethanol. The suspension was then sonicated for 30 min in a Fisher Scientific FB15050 ultrasonic bath to get a well-dispersed solution. The glassy carbon macro electrode (GCE, diameter = 3.02 ± 0.005 mm) was polished carefully using alumina with decreasing particle sizes of 1.0, 0.3 and 0.05 μm (Buehler, IL, UK) in turn on soft lapping pads (Buehler, UK), followed by rinsing with ultra-pure water and drying with nitrogen. The freshly polished GCE was modified by drop-casting a 2 μL (0.2 μg of MWCNTs-NH₂) suspension of MWCNTs-NH₂ and left to dry under vacuum. Cyclic voltammetry (CV) was carried out in a Faraday cage at 298 K using an EC-Lab potentiostat (SP-200 with ultra-low current module, Biologic Science Instruments, France). A conventional three-electrode system was operated with a MWCNTs-NH₂ modified GCE as the working electrode, a saturated calomel electrode (SCE, ALS distributed by BASi Inc., Japan) used as the

reference electrode and a graphite rod as the counter electrode. Based on the same procedure as above, MWCNTs modified GCEs were prepared again with 0.2 μg of MWCNTs *via* drop casting and studied voltammetrically in an analogous way to the MWCNTs-NH₂ modified GCEs.

To investigate the electrochemical oxidative peak current obtained by MWCNTs and MWCNTs-NH₂ modified GCEs at variable pH, CVs were conducted by immersing a freshly prepared MWCNTs modified GCE or MWCNTs-NH₂ modified GCE respectively in a 1.0 M HNO₃ (pH = 0.3), 0.1 M HNO₃ (pH = 1.0) and 0.1 M KNO₃ solution at different pH values of 2.0, 2.5, 3.0, 3.5, 4.0, 5.0 and 6.4 by changing the addition amount of 0.1 M HNO₃ or 0.1 M KOH under degassed conditions as above. The potential window was chosen as +0.1 V to +2.0 V *vs.* SCE. The voltammograms were recorded at a scan rate of 50 mV s⁻¹. A control experiment was also performed in the same solution but on a bare GCE.

To determine the voltammetric signals from the oxidation of MWCNTs and MWCNTs-NH₂ quantitatively, the peak current was found using OriginPro 2020 after background correction of the raw cyclic voltammograms. This is illustrated in Fig. S10 (ESI Section 13[†]), where a baseline spline is fitted between the potentials at which the voltammetric wave is judged to have started and ended, then subtracted from the peak to obtain the actual peak height.

To investigate possible surface functional group formation on electro-oxidation voltammetry, CV was conducted using MWCNTs or MWCNTs-NH₂ modified GCE in 0.1 M KNO₃ (pH = 6.4) by first sweeping from +0.10 V to +1.78 V then applying a fixed potential of +1.78 V for 0 s, 50 s, 100 s and 200 s respectively. After that, the potential was swept from +1.78 V to -1.50 V and back to +1.0 V under degassed conditions as above. The voltammograms were recorded at a scan rate of 50 mV s⁻¹.

Nano-impact experiments of MWCNTs and MWCNTs-NH₂

Nano-impact experimental measurements were performed by chronoamperometry using an EC-Lab Biologic potentiostat where the charge passed during the impact events was conserved. A carbon micro-disc electrode of nominally 33 μm diameter (IJ Cambria Scientific Ltd, UK) was used as the working electrode. Before each experiment, it was polished as described above. Pure MWCNTs was separately dispersed into 0.1 M HNO₃ (pH = 1.0) and 0.1 M KNO₃ (pH = 6.4) to form a uniform suspension (0.1 mg/10 mL) after 30 minute sonication. Then the measurements of current at various potentials in the range from 1.4 V to 2.0 V *vs.* SCE ("chronoamperometry") were performed on the 0.1 M KNO₃ (pH = 6.4) solution containing dispersed MWCNTs after bubbling with nitrogen for 10 minutes. An atmosphere of nitrogen was maintained during the experiments. Control experiments were conducted in the presence of 0.01 g L⁻¹ MWCNTs-NH₂ suspension. The effect of pH condition on the chronoamperometric current spikes and steps produced was investigated by placing the freshly polished carbon micro-disc electrode into 1.0 M HNO₃ (pH = 0.3), 0.1 M HNO₃ (pH = 1.0) and 0.1 M KNO₃ solution at different pH values of 0.3, 1.0, 1.8, 2.4, 2.7, 3.6, 4.1, 5.3 and 6.4 (adjusted by

a small addition of 0.1 M HNO₃ or 0.5 M KOH) containing 0.01 g L⁻¹ MWCNTs-NH₂ suspension or not. The data analysis program "Signal Counter" (Centre for Marine and Environmental Research, Zagreb, Croatia)⁵¹ was employed for making impact spike identification and individual spike charge determination. Counting and analysis of the impact step signals were performed in OriginPro 2020.
