Machine learning transferable atomic forces for large systems from underconverged molecular fragments†

 Marius Herbold ^a and Jörg Behler ^{*b}

Machine learning potentials (MLP) enable atomistic simulations with first-principles accuracy at a small fraction of the costs of electronic structure calculations. Most modern MLPs rely on constructing the potential energy, or a major part of it, as a sum of atomic energies, which are given as a function of the local chemical environments up to a cutoff radius. Since analytic forces are readily available, nowadays it is common practice to make use of both, reference energies and forces, for training these MLPs. This can be computationally demanding since often large systems are required to obtain structurally converged reference forces experienced by atoms in realistic condensed phase environments. In this work we show how density-functional theory calculations of molecular fragments, which are too small to provide such structurally converged forces, can be used to learn forces exhibiting excellent transferability to extended systems. The general procedure and the accuracy of the method are illustrated for metal–organic frameworks using second-generation high-dimensional neural network potentials.

1 Introduction

In recent years, machine learning potentials (MLPs)^{1–7} have become an important tool for atomistic simulations like molecular dynamics (MD) and Monte Carlo (MC), because they allow transfer of the accuracy of electronic structure calculations, most prominently density functional theory (DFT), to much larger systems containing thousands of atoms at a small fraction of the computational costs. Hence, the development of MLPs is a very active field of research and several generations have been proposed to date depending on the types of systems they can be applied to and the physical phenomena they are able to describe.^{8,9} Almost all MLPs applicable to large systems rely on atomic properties, which depend on the local environment up to a given cutoff radius R_c . As proposed in 2007 by Behler and Parrinello with the introduction of high-dimensional neural network potentials (HDNNP),^{10,11} in second-generation MLPs these

properties are the atomic energies E_i of atoms i , which according to

$$E = \sum_{i=1}^{N_{\text{atom}}} E_i, \quad (1)$$

yield the total potential energy E of the system. In third^{12–16} and fourth-generation^{17–19} MLPs this short-range energy can be augmented by long-range electrostatics, but still the atomic energies remain an essential component of most modern MLPs.

Nowadays, many types of second-generation MLPs are available, like various forms of neural network potentials,^{10,20–22} Gaussian approximation potentials (GAPs),^{23,24} moment tensor potentials (MTPs),²⁵ spectral neighbor analysis potentials (SNAPs),²⁶ atomic cluster expansion (ACE)²⁷ and many others.^{28,29} They have been applied with great success to numerous systems, and to date they have remained the dominant type of MLP applied in large-scale simulations.

A consequence of the cutoff defining the local atomic environments is the possibility to use small systems accessible in electronic structure calculations for training MLPs. These can then be applied to simulations of much larger systems, which has been demonstrated, *e.g.*, for metal clusters providing bulk properties,^{30,31} molecular fragments representing extended systems,^{32–34} and clusters of water molecules describing the liquid phase.^{35,36} This strategy does not only decrease the computational effort enabling the use of more accurate

electronic structure methods but also reduces the complexity of the configuration space to be sampled to the energetically relevant degrees of freedom.

Still, the generation of the reference data is the most time-consuming part in the development of MLPs, and thus identifying the smallest possible systems which provide all required information about the atomic interactions, *i.e.*, the potential-energy surface (PES), is of high interest. This is not only important for the generation of initial training sets but in particular also for the systematic improvement of MLPs by active learning.^{30,37–43} In the latter case the missing atomic environments are typically identified in production simulations, *i.e.*, using systems which are often too large for the direct application of electronic structure methods. Consequently, strategies for reducing the systems to the most essential structural features still containing the required information are needed.

Nowadays it is common practice to employ energies and forces to train MLPs,^{30,44–46} which allows to extract a lot of information from electronic structure calculations. Several procedures have been proposed in the literature to determine the cutoff radius required for obtaining converged atomic forces. In a study on the development of a GAP for carbon, a statistical approach has been suggested in which the local environment of the atom of interest is frozen while the positions of the atoms outside the cutoff sphere are modified.⁴⁷ For a sufficiently large cutoff radius there is only a negligible influence of these displacements on the variance of the forces of the central atoms.

Here, we build on an alternative approach making use of the Hessian, which provides the analytic derivatives of the forces.⁴⁸ This method allows to identify the influence of each individual atom in the system on a given force of interest, and a rigorous procedure to determine the required reference system size can be established for a desired degree of force convergence. This system size can be expressed in terms of a converged fragment radius $R_{\text{frag}}^{\text{conv}}$ including all neighboring atoms that have to be included for obtaining accurate forces in electronic structure calculations. If molecular or cluster fragments of this size are used, training of MLPs can be performed with forces numerically corresponding to those in much larger, condensed systems. Further details about this method can be found in ref. 48.

In the present work we show that the use of such converged fragments is not necessarily required for constructing MLPs and that it is possible to further decrease the size of the reference systems to about $\frac{1}{2}R_{\text{frag}}^{\text{conv}}$. Assuming three-dimensional systems with a homogeneous distribution of atoms, the volume and thus the number of atoms can be reduced by approximately a factor of eight. This results in a drastic reduction of the computing time in electronic structure calculations, which often have a very unfavorable scaling with respect to system size.

Our approach is based on the insight that, as detailed below, the analytic atomic forces corresponding to the total energy expression eqn (1) depend on up to twice the cutoff radius defining the atomic energy contributions in MLPs.¹¹ On the other hand, if converged electronic structure forces of bulk-like environments shall be learned directly, often large fragments

with radii of about 8–12 Å are required in electronic structure calculations. Here we show that as a consequence of the relation between forces and atomic energies molecular fragments of only about half this radius (with a numerical value depending on the specific system) are sufficient to extract the relevant information needed to predict accurate MLP forces in systems of arbitrary size. This is possible although these small fragments, which fully define the atomic energies according to eqn (1), yield numerical reference forces strongly differing from the target forces in the condensed phase, since the atomic environments are incomplete with respect to the information needed to obtain bulk-like forces.

We illustrate our approach using the iso-reticular metal-organic framework IRMOF-1 (also called MOF-5), and generalize our findings by including also some data for the larger systems IRMOF-10 and IRMOF-16.⁴⁹ MOFs are nanoporous, crystalline materials consisting of two parts – organic linker molecules, which interconnect inorganic secondary building units (SBUs) – with a large diversity of possible linker molecules and SBUs.^{49–53} The simulation of MOFs is a challenging task due to their often large unit cells. Furthermore, postsynthetic modifications^{50,54,55} and functionalizations^{50,56} increase the structural variety of MOFs. Hence, MOF properties can be designed for many different applications like gas storage, separation, catalysis and optical devices.^{50,56–59} Consequently, theoretical studies are of high interest for the analysis and prediction of MOF properties,⁶⁰ and reliable and accurate interatomic potentials are urgently needed.^{61,62} Accordingly, several MLPs for MOFs have been reported in the literature to date.^{33,63,64}

For our benchmark study, two types of HDNNPs are constructed based on either converged fragments providing bulk-like DFT reference forces, or making use of smaller fragments of about half this diameter yielding forces strongly differing from the bulk material. We show that in both cases HDNNPs of comparable quality can be obtained predicting reliable forces suitable for simulations of large systems.

2 Methods

In this work we demonstrate our approach using high-dimensional neural network potentials of the second generation.^{10,11} Starting from the total energy expression in eqn (1), the atomic energy contributions are provided as outputs of separate atomic feed-forward neural networks, which have the same architecture and set of numerical weight parameters for a given element. Accordingly, each element-specific atomic neural network has to be evaluated as many times as atoms of the respective chemical species are present in the system resulting in a close-to linear scaling of the method.

The input vectors of the individual atomic neural networks consist of descriptors containing the structural information about the respective atomic environments up to the cutoff radius. They need to take into account the mandatory permutation, translation and rotation invariances of the atomic energies. In the present work atom-centered symmetry functions

(ACSF) are used for this purpose,⁶⁵ which smoothly decay to zero in value and slope at the cutoff radius.

In the iterative training process the weight parameters of the atomic neural networks are adjusted to accurately reproduce total energies and forces for a given reference data set obtained from electronic structure calculations. No energy partitioning is required in the process since the total potential energy is automatically distributed among the atoms during the weight optimization. Simultaneously, also the available force information can be used to optimize the weights, since the analytic forces depend on the same weight parameters as the atomic energies.

For HDNNPs, the atomic force components acting on atom A with respect to the Cartesian coordinate R_A^α with $\alpha = \{x, y, z\}$ are given by

$$\begin{aligned} F_A^z &= -\frac{\partial E}{\partial R_A^z} = -\sum_{i=1}^{N_{\text{atom}}} \frac{\partial E_i}{\partial R_A^z} \\ &= -\sum_{i=1}^{N_{\text{atom}}} \sum_{j=1}^{N_{\text{sym}}} \frac{\partial E_i}{\partial G_{ij}} \frac{\partial G_{ij}}{\partial R_A^z}, \end{aligned} \quad (2)$$

where the chain rule has been applied to take into account the intermediate mapping of the atomic Cartesian coordinates onto the N_{sym} ACSFs $\{G_{ij}\}$. The first derivative is given by the architecture of the atomic neural networks, while the second term is provided by the definitions of the ACSFs.⁶⁵ Further details about HDNNPs and their properties can be found in several recent reviews.^{9,66,67} An interesting consequence of the analytic forces in eqn (2) is that the force components of atom A depend on the energies of all atoms inside its cutoff sphere, which in turn also depend on all neighboring atomic positions in their respective cutoff spheres. This results in a functional coupling of the position of atom A even with rather distant atoms B, as illustrated in Fig. 1a for IRMOF-1, extending the structural dependence of the

F_A^z up to twice the cutoff radius R_c of the ACSFs defining the atomic environments and thus the E_i . Consequently, for obtaining numerically bulk-like HDNNP forces the atomic environments need to be equivalent to the bulk environments up to $2 \cdot R_c$. This value corresponds to the converged fragment radius $R_{\text{frag}}^{\text{conv}}$ providing bulk-like DFT force that can be rigorously determined using the methodology described in ref. 48. This relation finally allows to determine the minimum value of R_c by DFT calculations for the specific system of interest.

However, since according to eqn (2) the individual force components consist of the derivatives of the atomic energies, in principle it should be possible to derive the forces in extended bulk-like environments from atomic energies defined by all neighbors within R_c only. Therefore, training HDNNPs with information restricted to the close atomic environments within R_c only should be sufficient to describe the PES even in the condensed phase.

The procedure to derive such a HDNNP for a given system consists of several steps. First, DFT calculations can be used to determine $R_{\text{frag}}^{\text{conv}}$, *i.e.* the physical interaction range, providing converged bulk-like forces. Then, it is possible to derive the minimal cutoff $R_c = \frac{1}{2} R_{\text{frag}}^{\text{conv}}$ required in the HDNNP to define the atomic energies. DFT calculations for fragments of this reduced size can then be used to train a HDNNP. This HDNNP, which consequently has not been trained to fragments large enough to contain bulk-like forces, should then be transferable to extended systems. In the present work we will demonstrate this workflow for the case of metal–organic frameworks.

3 Computational details

All DFT calculations reported in this work have been carried out using the FHI-aims code⁶⁸ (release version 171221). FHI-aims is an all-electron code employing a numerical atomic

Fig. 1 (a) Illustration of the environment-dependence of the atomic forces in bulk IRMOF-1. While the atomic energy E_A of carbon atom A only depends on the positions of the neighboring atoms within a sphere of radius R_c (red circle), the force vector F_A depends on all atomic positions in a sphere of radius of up to $2R_c$ (dotted circle). The reason for this extended range is the definition of the force as the negative derivative of the total energy, which according to eqn (2) consists of the derivatives of all atomic energies depending on the coordinates of atom A. Since in turn these atomic energies involve atoms as far as $2R_c$ from atom A (as shown by the yellow sphere of atom B). Atoms beyond twice the cutoff radius do not interact with atom A. Panel (b) shows a large molecular fragment (fragment radius $R_{\text{frag}}^{\text{conv}} = 8.718 \text{ \AA}$) providing converged DFT forces at the central atom A, closely approximating the forces in the periodic bulk system. The fragment has been constructed by removing all atoms beyond the dashed black lines shown in (a) following the procedure described in ref. 48. Panel (c) shows a much smaller fragment with about half fragment radius ($R_{\text{frag}} = 4.359 \text{ \AA}$) containing only atoms within R_c .

orbital basis, which is determined in free atom calculations. The RPBE functional⁶⁹ has been employed to describe electronic exchange and correlation in combination with dispersion corrections according to the method of Tkatchenko and Scheffler.⁷⁰ Furthermore, relativistic corrections were included by the atomic zero-order regular approximation (ZORA).⁶⁸

The DFT parameters were chosen to converge total energy differences to about 1 meV per atom. For all elements the basis set includes the FHI-aims recommended functions of the minimal basis, the functions of tier 1 and the first basis function of tier 2. The confinement potential has a width of 2 Å at the onset radius of 4 Å. The number of radial shells of the numerical integration grid corresponds to the element-specific tight settings. The angular integration grids and the atom-centered charge density expansion are equivalent to the light settings. For the calculations of the large periodic IRMOF bulk structure the Γ point has been used, while molecular fragments have been computed without periodic boundary conditions. The applied convergence criteria for the self-consistent calculations are 10^{-4} , 10^{-2} eV, 10^{-6} eV and 10^{-2} eV Å⁻¹ for the electron density, the energy eigenvalue sum, the total energy, and the atomic forces, respectively. For structural optimizations, the Broyden–Fletcher–Goldfarb–Shanno (BFGS) algorithm⁷¹ has been employed using an atomic force convergence criterion of 10^{-2} eV Å⁻¹.

The HDNNPs have been trained using the program RuNner^{11,66} employing two hidden layers containing 15 neurons each in the atomic neural networks. The hyperbolic tangent and a linear function have been used as activation functions for the hidden layers and the output node, respectively. The parameters of the ACSFs are given in the ESI.† A global extended Kalman filter has

been applied for optimizing the weight parameters⁷² using reference energies and forces. The reference data set has been split in 90% training data set and 10% test data set.

The IRMOF structures investigated in this work (Fig. 2) contain the same zinc-oxo-cluster SBU and share the overall topology. The only difference is in the linker molecule, which is benzene-1,4-dicarboxylate (BDC) in IRMOF-1, biphenyl-4,4'-dicarboxylate (BPDC) in IRMOF-10, and terphenyl-4,4''-dicarboxylate (TPDC) in IRMOF-16. Initially, the atomic positions and lattice parameters of the IRMOF bulk structures have been optimized by DFT. The geometrically nonequivalent atoms of IRMOF-1, -10, and -16 are shown in the lower part of Fig. 2, and the initial training structures consist of molecular fragments cut from the bulk centered at these atoms. These fragments have then been saturated by hydrogen following the procedure described in ref. 48. Two different fragment radii have been employed as shown in Fig. 1b and c. The larger radius $R_{\text{frag}}^{\text{conv}} = 8.718$ Å corresponds to the converged radius providing bulk-like DFT forces with a maximum error of 0.125 eV Å as determined in ref. 48. and is equivalent to $2 \cdot R_c$, while the smaller radius $R_{\text{frag}} = 4.359$ Å corresponds to R_c . The value of $R_{\text{frag}}^{\text{conv}} = 8.718$ Å has been identified in previous work using an analysis of the DFT Hessian, which provides the second derivatives of the energies or the first derivatives of the energy gradients (negative forces) with respect to the atomic coordinates. This allows to decompose the Hessian into 3×3 submatrices containing the information about the dependence of a force vector on the Cartesian coordinate vector of any other atom. The norm of this Hessian submatrix then allows to quantify this interaction by a single number that can be related

Fig. 2 Bulk unit cells of IRMOF-1, -10, and -16 and definitions of the in-equivalent atomic sites in the lower panels. Atoms have been colored by element (zinc: violet, oxygen: red, carbon: grey, hydrogen: white).

to the error in the force when truncating the system beyond the respective neighboring atom. For a series of model systems we found that this relation is rather universal and can be applied to determine the interaction range for a desired level of force convergence.

The required training structures have been generated initially by molecular dynamics simulations of the fragments in vacuum followed by active learning of bulk systems using the *RuNNerActiveLearn* tool.^{73,74} The second HDNNP required for the active learning has been constructed using 2 hidden layers containing 20 neurons per layer. Molecular dynamics simulations in the *NPT* ensemble (1 bar, 300–1000 K, 1 fs time step, 200 ps simulation time) employing preliminary potentials have been carried out with the *n2p2* program package⁷⁵ and the *LAMMPS* code⁷⁶ to generate IRMOF bulk geometries, which have then been searched by active learning for structures with forces deviating substantially between different preliminary HDNNPs. The applied selection criterion has been a force deviation of $1 \text{ eV } \text{Å}^{-1}$. Fragments have then been cut from the bulk centered at these atoms and included in the reference set. Moreover, atomic environments giving rise to extrapolations beyond the covered ACSF values have also been included in the data set.

4 Results and discussion

4.1 General strategy

For the construction of the HDNNPs we have combined data for all three MOF systems. Three different setups have been used to investigate the role of the fragment radius of the DFT reference structures and of the symmetry function cutoff radius describing the atomic environments in the HDNNP:

- HDNNP1 is based on DFT calculations of small molecular fragments with $R_{\text{frag}} = 4.359 \text{ Å}$ only, which are too small to provide converged bulk-like forces. Due to this small size only a small cutoff $R_c = 4.359 \text{ Å}$ can be applied in the construction of the HDNNP, since otherwise the atomic environments of the central atoms would be incomplete inside their cutoff spheres. This incompleteness would result in extrapolations when applying the potential to large periodic systems. The molecular fragments centered at the nonequivalent atomic sites are shown in Fig. 3. The upper part of Table 1 contains a compilation of the number of atoms and the number of central atoms in complete environments within a sphere of radius $R_c = 4.359 \text{ Å}$ for all fragments. HDNNP1 is constructed to answer the question if small fragments

Table 1 Numbers of atoms N_{atom} , numbers of central atoms N_{central} with complete environments up to the cutoff radius $R_c = 4.359 \text{ Å}$, and their ratio $N_{\text{central}}/N_{\text{atom}}$ for the small fragments ($R_{\text{frag}} = 4.359 \text{ Å}$, Fig. 3) and the extended large fragments ($R_{\text{frag}}^{\text{conv}} = 8.718 \text{ Å}$, Fig. 5)

	Small fragments					
	I1-As	I1-Bs	I10-Bs	I16-Cs		
N_{atom}	59	42	49	32		
N_{central}	17	11	17	16		
$N_{\text{central}}/N_{\text{atom}}$	0.29	0.26	0.35	0.5		
N_{atom}						
	Extended large fragments

N_{atom}	107	146	149	156	209	38
N_{central}	65	62	101	68	161	24
$N_{\text{central}}/N_{\text{atom}}$	0.61	0.42	0.68	0.44	0.77	0.63
N_{atom}						

are indeed sufficient to construct a potential for the condensed system.

- HDNNP2 is trained to large molecular fragments constructed using the radius $R_{\text{frag}}^{\text{conv}} = 8.718 \text{ Å}$, which provide structurally converged DFT forces numerically corresponding to bulk forces in the condensed phase. The original fragments are shown in Fig. 4. Since several of these fragments exhibit a rather small number of bulk-like atoms with converged DFT forces, the fragments have been slightly extended as displayed in Fig. 5 to achieve a more favorable bulk atom-to-surface atom ratio (*cf.* Table 2). These extended fragments have finally been used for training HDNNP2. Still, the same small symmetry function cutoff $R_c = 4.359 \text{ Å}$ as in case of HDNNP1 is applied, which results in a rather large number of central atoms with complete environments within R_c as listed in the lower part of Table 1. HDNNP2 will allow to answer the question if a small cutoff radius is sufficient in combination with fully converged reference DFT forces to describe the bulk.

- Finally, HDNNP3 is trained using the same extended, size-converged molecular fragments ($R_{\text{frag}}^{\text{conv}} = 8.718 \text{ Å}$) as HDNNP2, but applying an increased symmetry function cutoff $2R_c = 8.718 \text{ Å}$ such that all information required to compute numerically bulk-like forces using HDNNP3 is available. The number of central atoms embedded in complete environments with this extended cutoff is given in the bottom part of Table 2. HDNNP3 will serve as reference potential trained to converged DFT data making use of all structural information relevant for the DFT forces.

Our goal is now to investigate by comparing these HDNNPs, if the information content of the small molecular fragments, which fully define the atomic energies but not the forces in a bulk-like environment, is sufficient to accurately represent the PES of large condensed systems. In this case HDNNP1, HDNNP2 and HDNNP3 should be of similar quality, and the use of small fragments with a radius rigorously derived from DFT calculations⁴⁸ would allow to drastically reduce the computational effort for the generation of the reference data. Our focus is on IRMOF-1, but also data of IRMOF-10 and IRMOF-16 is included to generalize our findings, although we do not aim

Fig. 3 Small molecular fragments for IRMOF-1, -10, and -16 covering all nonequivalent atomic sites. to construct comprehensive PESs for atomistic simulations of these systems here.

4.2 High-dimensional neural network potentials

4.2.1 Construction of HDNNP1. For the small fragments, the cutoff radius of the ACSFs has been set to $R_c = 4.359 \text{ \AA}$. For each element combination initially five radial ACSFs have been defined, while for the angular ACSFs eight different sets of parameters have been chosen per element combination. To reduce the total number of ACSFs we analyze the DFT Hessian

following our procedure described in ref. 48. This analysis provides individual maximum interaction distances for each atomic site for a desired level of force accuracy. We find only negligible interactions between zinc and distant hydrogen atoms, as well as only small hydrogen–hydrogen and hydrogen–oxygen interactions (see Section S-I, ESI[†]), resulting in a set of 20 radial ACSFs for the carbon atoms, 18 radial ACSFs for the oxygen atoms, 15 radial ACSFs for the zinc atoms, and 11 ACSFs for the hydrogen atoms. The details of these radial ACSFs are given in Table SII in the ESI[†]. The parameters of the angular ACSFs are given in Table SIII (ESI[†]).

An initial training data set (“HDNNP1-initial”) has been generated from *ab initio* MD simulations at 600 K and a time-step of 1.5 fs for the four small fragment structures in vacuum (*cf.* Fig. 3), resulting in 3498 structures (I1-As: 682, I1-Bs: 908, I10-Bs: 908, I16-Cs: 1000) with their associated energies and forces. A first preliminary HDNNP represents this initial data with a good accuracy, exhibiting low root mean squared errors (RMSE) for the energies of the training ($E^{\text{train}} = 0.0012 \text{ eV atom}^{-1}$) and test data set ($E^{\text{test}} = 0.0013 \text{ eV atom}^{-1}$), as well as acceptable errors for the force components of the training ($F^{\text{train}} = 0.1436 \text{ eV \AA}^{-1}$) and test data set ($F^{\text{test}} = 0.1453 \text{ eV \AA}^{-1}$), respectively (upper part of Table 3). Also the individual RMSEs of the fragments I1-As, I1-Bs and I10-Bs are small, while the errors for the I16-Cs fragment are only moderately larger.

Based on this initial HDNNP1, the training data set has been iteratively expanded by active learning using MD simulations of bulk systems and cutting fragments around atomic sites with

forces different substantially between different HDNNPs. The final data set consists of 13 220 structures (11 875 training and 1345 test structures) and has been used for the training of the final HDNNP1, which shows slightly increased RMSEs for the training and test set energies due to the larger diversity of structures to be covered, while the representation of the forces is improved (lower part of Table 3) indicating a smooth PES with essentially no overfitting, which is also supported by the nearly identical energy RMSEs of the training and the test set.

4.2.2 Construction of HDNNP2 and HDNNP3. In order to generate training data for the larger fragments with radius $R_{\text{frag}}^{\text{conv}} = 8.718 \text{ \AA}$ (cf. Fig. 5), instead of running initial *ab initio* MD of the fragments in vacuum we can now employ the initial HDNNP1 to perform efficient dynamics of the bulk directly to determine the large fragments by active learning. The selected training structures have then been recomputed by DFT and used for the iterative refinement of HDNNP3. The same data set finally obtained has then been used also for the construction of HDNNP2.

The final DFT data set consists of 13 503 fragment structures, which have been split into a training and a test set containing 11 875 and 1345 fragments, respectively. For HDNNP2, the same small cutoff and ACSFs as for HDNNP1 (Tables SII and SIII, ESI[†]) have been employed, and consequently for the training of HDNNP2 a strongly increased number of central atoms with completely filled cutoff spheres is available in the reference set. Moreover, the large fragment radius now also allows to make use of a larger symmetry function cutoff of $2R_c = 8.718 \text{ \AA}$, which we have employed in HDNNP3. This cutoff includes all neighboring atoms, which are relevant to obtain converged bulk-like forces in DFT calculations. To ensure a radial resolution of the ACSFs comparable to HDNNP1 and HDNNP2, 17 radial ACSF have been defined for each element combination, while again zinc–hydrogen

interactions are omitted, and a reduced number of radial functions is used to describe hydrogen–hydrogen and hydrogen–oxygen pairs resulting in 68 radial ACSFs for carbon atoms, 54 for oxygen atoms, 51 for zinc atoms, and 23 for hydrogen atoms. The angular ACSFs for all element combinations are constructed in analogy to the ACSFs of HDNNP1 and HDNNP2. The parameters of all symmetry functions of HDNNP3 are given in Tables SIV, SV and SVI in the ESI.[†]

The RMSEs of the energies and force components of all large fragments are compiled in Table 4 for HDNNP2 and HDNNP3. Several comments should be made at this point. First, for both, HDNNP2 and HDNNP3, the accuracy of the fragment energies in the test set is essentially the same as for HDNNP1 (HDNNP2: 0.0011 eV per atom, HDNNP3: 0.0012 eV per atom), which shows that that the representation of the PESs of the small and the large fragments is of similar quality. Moreover, increasing the cutoff radius, *i.e.*, the amount of information about the atomic environments, in HDNNP3 compared to HDNNP2 does not have a notable influence on the description of the PES. The increased structural complexity of the extended atomic environments to be learned by HDNNP3 seems to be well represented by the increased set of ACSFs. Still, the effective number of bulk-like atomic environments inside R_c in HDNNP2 (1 051 611 atomic environments) is substantially larger than in case of HDNNP3 (400 885 atomic environments), since in case of the large cutoff less atoms are surrounded by completely filled cutoff spheres.

Both, the RMSEs of the energies and forces of HDNNP2 and HDNNP3, are very similar for the data in the training and in the test set indicating the absence of overfitting. The accuracy of the forces is slightly reduced compared to HDNNP1, but it should be noted that the reference forces are different in the larger fragments underlying HDNNP2 and HDNNP3, and also the number of topologically different fragments is increased as

Table 3 RMSEs of the potential energy E^{train} and E^{test} in eV per atom as well as of the force components F^{train} and F^{test} in eV \AA^{-1} for HDNNP1 constructed for the small fragments (cf. Fig. 3) employing a small cutoff $R_c = 4.359 \text{ \AA}$. The values in the lines "initial" and "final" correspond to the RMSE values of the complete data sets used in the training of initial preliminary HDNNP1 as well as the final potential. In addition, the RMSEs of the individual fragments are also given

there are six fragment types for the large radius and only four different types of small fragments. Similar to HDNNP1, the largest force errors in HDNNP2 and HDNNP3 are found for the atomic sites of the central phenyl rings in the TPDC linker of IRMOF-16 indicating the relatively long-ranged interactions mediated by the aromatic system.

4.3 Validation using molecular fragments

So far, the accuracy of the energies and forces has been investigated for the training and test data sets. Since some of these structures have been generated by MD simulations of the fragments in vacuum, conformational changes in these simulations might result in geometrical differences from the atomic environments in the bulk MOFs. In order to assess the performance of HDNNP1, HDNNP2, and HDNNP3 for fragments in exclusively bulk-like geometries, HDNNP1 has been employed to run MD simulations of the bulk crystals of IRMOF-1, -10, and -16. Then, for each IRMOF, 251 bulk structures have been created at 200 K and additionally at 500 K for IRMOF-1, at 450 K for IRMOF-10 and at 350 K for IRMOF-16, respectively. In this way, structures exhibiting atomic forces up to $\approx 8 \text{ eV \AA}^{-1}$ have been obtained for each system, which provide an unbiased assessment of the accuracy of the HDNNPs, since these structures have not been involved in the active learning process.

From these bulk structures, in total 3514 small validation fragments with $R_{\text{frag}} = 4.359 \text{ \AA}$ have been cut (I1-As: 1506, I1-Bs: 502, I10-B2: 1004, and I16-Cs: 502), saturated by hydrogen and recomputed by DFT in the bulk-like geometries. The resulting energies and forces have been compared to the predictions of HDNNP1 and HDNNP2, and the corresponding RMSEs are compiled in Table 5. Note that HDNNP3 is not applicable to these small fragments since the atomic spheres resulting from the large symmetry function cutoff would not be completely filled by the small fragments resulting in extrapolation of the potential. Overall, we find energy and force RMSEs of the

validation structures, which are even slightly smaller than those of the small training and testing fragments in Table 3. This might be caused by the more homogeneous structures in bulk-constrained geometries, which do not contain strongly distorted fragments that might occur in vacuum MD simulations and are more difficult to learn.

For computing the RMSEs of the energies of the small validation fragments by HDNNP2, fragment-specific corrections had to be applied to remove possible constant total energy offsets as discussed in ref. 74. These offsets are a consequence of different stoichiometries of the investigated small fragments and of the large fragments underlying the construction of HDNNP2. The reason is the flexibility of the internal energy distribution in MLPs and offsets of varying size are commonly found in potentials trained to systems with a limited variation in the chemical compositions when applied to very different systems. The offset corrections have been determined by cutting the respective small fragment from the DFT optimized bulk structure and by subsequently computing the energy difference between DFT and HDNNP1 of this fragment. The same offset correction has then been used for all fragments of a given type. Forces, *i.e.* energy gradients, are not affected by such total energy offsets.

Similar results have also been found for the six large validation fragments (Table 5) in that all three HDNNPs provide energy and force RMSEs very similar to the training and testing data in Table 4. For HDNNP1, which has not been trained to large fragments, a similar offset correction has been applied.

In summary, all HDNNPs irrespective of the trained fragment radius and the cutoff of the symmetry functions are able to describe the energies and forces of molecular fragments in bulk geometries with high accuracy. Further, it is particularly interesting that even HDNNP1, which employs only a small cutoff and has not been trained using forces numerically corresponding to the forces in the condensed phase, provides an excellent description of the atomic forces in bulk-like environments. Of all three HDNNPs, HDNNP1 yields the lowest force RMSE for the validation set, which might be a consequence of the simplicity of the reduced configuration space in the small cutoff spheres facilitating the learning process.

4.4 Transferability to the bulk

Finally, we test the accuracy of all three HDNNPs for periodic bulk MOF structures. Before investigating the HDNNPs, we first compute the deviations in the DFT forces between the periodic bulk systems and the central atoms in the small and large molecular fragments. This analysis is of interest as it allows to quantify how close in value the DFT forces in the large fragments are with respect to the DFT forces in the bulk and to what extent the DFT forces in the small fragments, which have been used in the training of HDNNP1, differ from the periodic systems.

Fig. 6 shows the DFT force errors when comparing the central atoms of the large fragments with the bulk. Only a few fragments of types I1-A' and I10-A' exhibit deviations exceeding the selected force tolerance of $0.125 \text{ eV \AA}^{-1}$, up to

Table 5 RMSEs of HDNNP1, HDNNP2, and HDNNP3 for the energies (in eV per atom) and the force components (in eV \AA^{-1}) in the validation data cut from MD simulations of bulk IRMOF-1, -10, and -16. Due to the large ACSF cutoff radius $R_c = 8.718 \text{ \AA}$ of HDNNP3 no RMSE values are given for the small fragments (I1-As, I1-Bs, I10-Bs and I16-Cs) for HDNNP3, as these structures do not fill the entire cutoff spheres giving rise to extrapolations

Validation fragment	Validation points	HDNNP1		HDNNP2		HDNNP3

Fig. 6 Norm of the DFT force errors $\|\Delta F_A\|$ (in eV \AA^{-1}), i.e., the absolute difference between the force vectors in the periodic bulk structure and in the large fragments ($R_{\text{frag}}^{\text{conv}} = 8.718 \text{ \AA}$, cf. Fig. 5), for all central atoms in a bulk-like environment. The target accuracy for converged forces $\|\Delta F^{\text{max}}\| = 0.125 \text{ eV \AA}^{-1}$ (cf. ref. 48) is highlighted by the black line showing that the vast majority of atomic forces in the fragments is very similar to the periodic bulk system.

about $0.160 \text{ eV \AA}^{-1}$ at most, while the vast majority of force errors is substantially smaller underlining the good representation of bulk-like forces in the large fragments and confirming the converged fragment radius determined in ref. 48. The varying effective interaction ranges for the atomic sites in the different fragments are clearly visible in form of different plateaus. For instance, the atomic linker positions C2 (except in IRMOF-1), C3, C4, C5, C6, C7, H1, H2 and H3, which are mainly represented by the fragments I10-B', I16-B' and I16-C', are only weakly effected by the atomic environment outside the fragment radius (Table SI, ESI[†]) resulting in small atomic force errors.

The situation is different for the small fragments compiled in Fig. 7, which show clearly larger force errors. In particular a large number of I1-As fragments show prominent deviations up

Fig. 7 Norm of the DFT force errors $\|\Delta F_A\|$ (in eV \AA^{-1}), i.e., the absolute difference between the force vectors in the periodic bulk structure and in the small fragments ($R_{\text{frag}} = 4.359 \text{ \AA}$, cf. Fig. 3), for all central atoms with a complete environment within R_c . The criterion for converged forces $\|\Delta F^{\text{max}}\| \leq 0.125 \text{ eV \AA}^{-1}$ (conf. ref. 48) is highlighted by the black line showing that a significant part of the atomic forces in the fragments is substantially different from the periodic bulk system.

Table 6 Energy and force RMSEs (in eV per atom and eV \AA^{-1} respectively) of the predictions of HDNNP1, HDNNP2, and HDNNP3 for the bulk validation data sets with respect to DFT

Validation set	Data points	HDNNP1		HDNNP2		HDNNP3	
		RMSE		RMSE		RMSE	
		<i>E</i>	<i>F</i>	<i>E</i>	<i>F</i>	<i>E</i>	<i>F</i>
IRMOF-1 bulk	502	0.0009	0.1041	0.0008	0.1100	0.0014	0.1301
IRMOF-10 bulk	502	0.0014	0.1174	0.0010	0.1312	0.0009	0.1513
IRMOF-16 bulk	502	0.0015	0.1149	0.0008	0.1319	0.0016	0.1501

to about 0.35 eV \AA^{-1} . Therefore, it is evident that the small fragments do not provide bulk-like forces in DFT calculations and thus these forces could not be learned directly by HDNNP1, but can only be predicted based on the atomic energies.

Now we compute the energy and force RMSEs with respect to DFT of the 502 bulk validation structures for each MOF system using HDNNP1, HDNNP2, and HDNNP3. Again, a correction for the energy offset has been determined using the energy of the DFT optimized IRMOF bulk structures and the respective HDNNP predictions. The results are compiled in Table 6. All HDNNPs predict the bulk energies and atomic forces with excellent accuracy, with the largest force RMSE of 0.15 eV \AA^{-1} found for IRMOF-16 predicted by HDNNP3, which is the most challenging case due to the large atomic environments to be sampled and the smallest number of training fragments for this MOF in the reference data set. Overall, the energy and force errors are at least comparable and in most cases even clearly below the errors of the respective fragments in the training and test sets in Tables 3 and 4. Most importantly, HDNNP1 provides the smallest force errors of all HDNNPs demonstrating that indeed the PESs of the periodic bulk MOFs can be learned from small, underconverged molecular fragments without making use of numerically bulk-like forces.

4.5 Conclusion

In this work, we have shown for the example of high-dimensional neural network potentials that it is possible to train transferable second-generation MLPs yielding accurate forces for extended systems using only molecular fragments, which are too small to provide numerically converged bulk-like forces. The reason for this transferability from underconverged fragments to large systems is the analytic relation between the forces and the atomic energies, which have different formal interaction ranges with respect to the atomic environments. Since the forces can be derived as a sum of partial derivatives of the atomic energies, it is possible to predict accurate forces using the rather short-ranged environment-dependence of the atomic energies within the applied symmetry function cutoff only. A condition for this transferability of the forces is a rigorous determination of the system-specific physical interaction range, which can be determined from first principles for the case of the forces using the Hessian-based method reported in ref. 48. Then, half of this interaction range defines the minimum symmetry function cutoff of the atomic environments in the small

fragments, which corresponds to the fragment radius that has to be applied in the construction of the reference data set.

The absolute values of the fragment and cutoff radii depend on the system under investigation, and in the present work we have chosen the metal–organic–frameworks IRMOF-1, -10, and -16 for illustrating the feasibility of our approach. Moreover, the fragment radius depends on the desired level of accuracy of the forces. Following earlier work,⁴⁸ for simplicity we have adopted a force convergence level of about $0.125 \text{ eV \AA}^{-1}$ here. Applying a more rigorous convergence criterion is possible, which then results in larger reference systems but does not affect the general finding of our work in that smaller fragments of half the size are still sufficient for obtaining transferable potentials. Using such fragments of decreased size enables to drastically reduce the costs of the electronic structure reference calculations employed in the construction of MLPs.

Beyond these general considerations, we have shown that for the explicit example of a series of MOFs the generation of potentials with transferable forces is indeed possible. For this purpose, three different HDNNPs have been developed employing (1) small fragments and a small cutoff, (2) large fragments and a small cutoff, and (3) large fragments and a large cutoff. For all these potentials a similar accuracy for the energies and forces in independent validation sets consisting of large fragments and periodic bulk structures have been found, confirming the possibility to construct transferable potentials for real systems. Interestingly, overall the HDNNPs constructed using a small symmetry function cutoff even show a generally better accuracy, which might be a consequence of the increased structural complexity to be described in case of large cutoff spheres and the corresponding larger amount of information that has to be provided in the reference data set. Our results are general and applicable to all types of second-generation MLPs.
