Resistive graphene humidity sensors with rapid and direct electrical readout†

Anderson D. Smith,^a Karim Elgammal,^b Frank Niklaus,^{*c} Anna Delin,^{b,d,e} Andreas C. Fischer,^c Sam Vaziri,^a Fredrik Forsberg,^c Mikael Råsander,^{b,f} Håkan Hugosson,^b Lars Bergqvist,^{b,e} Stephan Schröder,^c Satender Kataria,^g Mikael Östling^a and Max C. Lemme^{*a,g}

We demonstrate humidity sensing using a change of the electrical resistance of single-layer chemical vapor deposited (CVD) graphene that is placed on top of a SiO₂ layer on a Si wafer. To investigate the selectivity of the sensor towards the most common constituents in air, its signal response was characterized individually for water vapor (H₂O), nitrogen (N₂), oxygen (O₂), and argon (Ar). In order to assess the humidity sensing effect for a range from 1% relative humidity (RH) to 96% RH, the devices were characterized both in a vacuum chamber and in a humidity chamber at atmospheric pressure. The measured response and recovery times of the graphene humidity sensors are on the order of several hundred milliseconds. Density functional theory simulations are employed to further investigate the sensitivity of the graphene devices towards water vapor. The interaction between the electrostatic dipole moment of the water and the impurity bands in the SiO₂ substrate leads to electrostatic doping of the graphene layer. The proposed graphene sensor provides rapid response direct electrical readout and is compatible with back end of the line (BEOL) integration on top of CMOS-based integrated circuits.

Solid-state gas sensors have become popular due to their low cost and scalability and have already found their way into a number of different applications.^{1,2} Current research focuses on sensors based on metal oxides,³ semiconductor nanowires,^{4–7} carbon nanotubes^{4,5} and, most recently, solid-state gas sensors based on graphene and graphene oxide (GO).^{8–19} One of the notable properties of graphene is its high electrical conductivity, which can be ascribed to the p-orbital electrons, which form π -bonds with neighboring atoms. These π -bonds with their de-localized electrons define the electronic

band structure⁸ with its high carrier mobility.^{20,21} However, the delocalized π -electrons are also sensitive to modifications of their immediate environment. As a consequence, graphene has been shown to be sensitive to a number of different gasses.^{22–26} It has also provided the ultimate level of sensitivity by detection of single gas molecules.²⁷ Several studies have previously been reported on the influence of humidity on graphene-based devices, but the results reported thus far are limited in range and/or response times.^{12,16,17,28,29} Here, we present rapid response resistive humidity sensing using CVD graphene placed on an SiO₂ layer for potential solid state sensor applications. The sensors are operational under atmospheric conditions with negligible cross-sensitivity from competing gasses. The humidity sensing mechanism is explained by interactions of the polar H₂O molecules with substrate (SiO₂) defects through density functional theory simulations. Chemical vapor deposited graphene was used and the sensor design allows easy integration with CMOS-based circuits, thereby offering a low-cost and highly scalable alternative to conventional humidity sensors for system-on-chip (SoC) solutions.^{48,49}

The process flow for fabricating graphene sensors is shown in Fig. 1a, and a detailed explanation of the fabrication is provided in the Methods section. The sensors are fabricated on silicon substrates with thermally grown, 300 nm thick SiO₂ layers (Fig. 1a-1). First, gold contacts are embedded in the

oxide (Fig. 1a-2) that can be used for four-point resistance measurements of the graphene patch (although other metals may be used). Chemical vapor deposited graphene³⁰ is then transferred from copper foils onto the substrate (Fig. 1a-3) and etched into the desired shape (Fig. 1a-4). The effective dimensions of the graphene patches are 44 μm in length (the distance between the inner Au contacts) and 80 μm in width. The Raman spectrum shows the typical graphene G and 2D peaks (Fig. 1b)³¹ and confirms the successful graphene transfer as well as the absence of a discernable defect peak, demonstrating that the graphene is of good quality. A more detailed explanation of the graphene quality is provided in the ESI.† The fabricated sensors are placed in ceramic packages and wire-bonded (Fig. 1c). Fig. 1c further shows a color enhanced scanning electron micrograph (SEM) of a device, with the single-layer graphene patch on top of the SiO₂, the gold contacts underneath the graphene patch and the bond wires connected to the bond pads.

The experiments were carried out inside two separate chambers: a vacuum chamber operating (Fig. 1d) at a pressure below atmospheric pressure and a humidity chamber (Fig. 1e) operating at atmospheric pressure. The two chambers were required to cover the full humidity range from 1% relative humidity (RH) to 96% RH. In the vacuum chamber, air is pumped out of the chamber, which reduces the water vapor

(i.e. the humidity level) from about 30% RH down to 1% RH. The rate at which the pump removes air out of the chamber is controlled by a valve. The vacuum chamber was also used to expose the graphene devices to individual gasses in a controlled way. This allows evaluation of the cross-sensitivity of the sensor to competing gasses. In contrast, the humidity chamber operates at constant atmospheric pressure and can be filled with water vapor to vary the humidity from approximately 30% RH to 96% RH. This is done through the use of a humidifier which pumps water vapor into the chamber through a pipe. The water vapor flow rate from the humidifier is controlled by a dial on its side. A real time electrical readout in labview shows the current device resistance and chamber humidity at all times during the measurement. While precise control of the chamber humidity is difficult, observation of the relative changes in humidity measured with respect to resistance provides sufficient precision. During all measurements, the humidity is continuously monitored using a commercial HIH-4000 humidity sensor (Honeywell International Inc.). In addition, the gas pressure in the vacuum chamber is continuously monitored using a commercial digital vacuum transducer PDR 900 (MKS Instruments). Further, the temperature is monitored using a LM35 commercial temperature sensor. In experiments where the temperature is monitored, graphene devices show little or no temperature dependency – neither

Fig. 2 (a) Resistance change in the graphene device *versus* the relative humidity (%RH) for a device placed in the vacuum chamber (1) and the same device placed in the humidity chamber (2). (b) Interaction of water molecules with the graphene surface. (c) Resistance response (black lines) of the graphene device in a Wheatstone bridge configuration in comparison with the %RH response from both a commercial HIH-4000 humidity sensor (red line) as well as pressure response (bar) from a commercial PDR 900 pressure sensor (blue line) placed in the vacuum chamber.

from convective cooling from incoming air flow nor from Joule heating (see the ESI†).

Fig. 2a shows the measured relative change in the resistance of the graphene sensor as the pressure chamber is evacuated (region 1, black symbols). The data are combined with the measured relative change in the resistance of the graphene sensor in the separate humidity chamber as the humidity is increased (region 2, blue symbols). Note that once the humidity begins to change, the resistance changes correspondingly and the response to change in humidity shows similar behavior in both chambers. As the humidity is decreased in the vacuum chamber by reducing the gas pressure, the corresponding resistance increases (Fig. 2a-1). Likewise, as the humidity is increased in the humidity chamber by introducing water vapor, the corresponding resistance decreases (Fig. 2a-2). Fig. 2b shows a schematic of the interaction of water vapor with the graphene. As the humidity increases, more water molecules are adsorbed on the surface. Likewise, a decrease in humidity will cause water molecules to be desorbed from the surface. For measuring the resistance of the graphene patch, the device is placed in a Wheatstone bridge configuration. The graphene patches are biased with square-wave pulses of 200 mV and a pulse duration of 500 μ s. This is done in order to mitigate a drift in the device due to excessive Joule heating. Fig. 2c compares the measurement data from a graphene sensor placed in the vacuum chamber (black line) with the measured relative humidity shown in the figure as a %RH value using the commercial humidity sensor (red line) and the

measured chamber pressure using the commercial pressure sensor (blue line). The output signals of the graphene humidity sensor and the commercial humidity sensor and the pressure are remarkably similar, confirming that the changes in the chamber pressure correlate with changes in the water vapor concentration in air.

A control experiment was conducted to rule out cross-sensitivities to pressure variations or to gasses typically present in air. Therefore, graphene devices were individually exposed to the most common gasses comprising air, including dry nitrogen (N₂), dry oxygen (O₂), and dry argon (Ar), as well as humid air. To achieve this, the pressure valve which controls the influx of air into the vacuum chamber was connected to a tank containing these pure and dry compressed gasses. Once connected, the valve to the gas tank was opened and the gas was allowed to enter the chamber. By evacuating the pressure chamber to a vacuum of less than 200 mbar for several minutes while allowing the influx of pure dry gas, the chamber was filled with the gas. For each gas, the resistance change in the graphene sensor was then recorded while varying the chamber pressure between 200 mbar and 1 bar. The pressure was controlled through a valve between the chamber and the vacuum pump (similar to the experiments reported by Smith *et al.*).³² The response of the graphene sensor as a result of varying pressure for each individual gas was determined and is summarized in Fig. 3a. Note that there is no significant change in resistance for any of the gasses tested individually. In contrast, the resistance change of graphene devices exposed

Fig. 3 (a) Normalized signal response of the graphene device for different gasses at varying pressures (resulting in varying humidities in the case of air). Note that the resistance change in the graphene devices is very small for any of the gasses, except for the case of air, which is the only gas containing an appreciable amount of water vapor. (b) Change of resistance in a graphene device exposed subsequently to various gasses (black dots) compared with the relative humidity levels (%RH) measured by using a commercial HIH-4000 sensor (red dots). Note that individual dry gasses have no effect on the resistance response of the graphene device. (c) Graphene device in air and subjected to pulses of N₂ flow. (d) Schematic representation of how N₂ flow over the device affects the local humidity levels. (e) Resistance response of a graphene device when exposed to inhaling and exhaling human breath. (f) Schematic representation of water vapor being blown onto the device as it is breathed on, thereby increasing the local humidity levels.

to humid air persists among the repeated trials. This strongly suggests that there is no influence of the individual gasses on the resistance of the graphene, but that it is indeed the humidity that is sensed.

The insensitivity of the sensor to the main gasses constituting air was further verified by connecting multiple gas supplies (dry Ar, dry N₂, dry O₂ and humid air) to the vacuum chamber and allowing each of the gasses to subsequently enter into the chamber. This confirms that none of the individual dry gasses has an effect on the graphene device when first introduced into the chamber. Fig. 3b shows the resistance evolution of the graphene sensor (black dots) measured as each gas was introduced into the chamber. First, the chamber was filled with Ar and then Ar was circulated through the chamber for about 60 s while the resistance response of the sensor was recorded. Then the argon flow was switched off and the chamber was evacuated. This procedure was repeated for N₂

and O₂. Finally, humid air was introduced in the chamber. Fig. 3b shows no significant resistance response of the graphene sensor while each gas is introduced into the chamber, except for the case of humid air. The corresponding %RH response of the commercial HIH-4000 humidity sensor (red dots) in Fig. 3b confirms that the humidity in the chamber is not significantly affected as dry gasses are being carefully circulated. This demonstrates that, within the time-scales of this study, each individual gas has very little effect on the resistance of the graphene device and that the graphene sensor has high-specificity for humidity in relation to the main gas constituents in air. This is in contrast to previous studies, which have reported the sensitivity of graphene to O₂, suggesting that there may be possible cross-sensitivity.³³ However, that study was carried out over larger timescales with slower response times than reported here, which may serve to explain the different conclusions.

The situation is slightly different when there is a substantial gas flow across the sensor, as there may be competing events. First, an N₂ gun was used to control the flow of nitrogen over the surface of the sensor. As the N₂ flows over the surface of the device, the resistance increases noticeably and reproducibly (Fig. 3c). This can be explained by a reduction of the surface concentration of water molecules on the graphene as illustrated in Fig. 3d. In a similar fashion, the device was exposed to a flow of exhaled breath with a relative humidity of approximately 100%. Fig. 3e shows the resistance response of a device while inhaling and exhaling breath several times in close proximity (within 10 cm) to the device. Here, exhaling (= flow on) leads to a decrease of the resistance. This result is in line with our expectations, because the device response is triggered by water vapor contained in the breath as illustrated in Fig. 3f. In both cases, the exposure to N₂ flow and the exposure to breath, an increase in water vapor concentration causes a decrease in the resistance of the graphene device, while a decrease in the concentration of water vapor causes an increase in the resistance of the graphene device. These results are expected and consistent with the results from the measurements in the vacuum and humidity chambers as shown in Fig. 2.

The repeatability is addressed in Fig. 4a, which shows the average measured graphene device resistance plotted *versus* relative humidity (%RH (red dots with a line)). The error bars indicate the standard deviation of the data from the averaged value, with a maximum standard deviation of 0.1082 Ω. The gray dots represent the raw data. These data represent three cycles of pumping and venting of humid air in and out of the pressure chamber. Fig. 4b compares the device conductivity, calculated with a simple resistor model based on the measured device dimensions and the known thickness of single-layer graphene of approximately 3.4 Å,³⁴ over time with the signal from the commercial humidity sensor. The data represent three cycles of modulating the humidity inside the vacuum chamber and show remarkably consistent readout. Previously reported data for humidity sensing using graphene suggest very slow response and recovery times on the order of 180 s.¹⁷ Fig. 4c and d show the time resolved response and recovery of the graphene sensor and the commercial humidity sensor. The response and recovery times are defined here as the time it takes for the signal to reach from 10% of the initial humidity value to 90% of the final humidity value. In Fig. 4c and d, the black dots represent the signal from the graphene sensor and the red dots represent the signal from the commercial humidity sensor. The 10% to 90% regions are marked with dashed black and red lines. Because the pumping and venting of water vapor in and out of the vacuum chamber involve a delay on the order of several seconds, it is not possible from the measurements performed in the vacuum chamber to precisely determine the absolute response and recovery times using this experimental set-up. Therefore, an N₂ gun was used to induce a more local and rapid change of surface water molecules (compare Fig. 3c and d). Fig. 4e and f show the response and recovery times in a graphene sensor from a flow-ON state to a

flow-OFF state and *vice versa*. The 10% to 90% regions are again marked with dashed red and blue lines. The measured response times are 600 ms to 800 ms and the recovery times are 400 ms to 1 s. Fig. 4g displays the resistance measurement of a device in the vacuum chamber from Fig. 4b in high time resolution, just when the chamber humidity begins to increase. The graphene sensor (black circles) clearly responds faster than the commercial humidity sensor (red dots). The shaded black and red regions represent the approximate time at which a shift from decreasing to increasing humidity is measured. Here, the graphene device responds approximately 1–2 seconds faster than the commercial sensor. The combination of these measurements suggests that the response and recovery times of the devices are on the order of milliseconds and are possibly much faster than observed due to limitations in the experimental setup.

The mechanism underpinning graphene's sensitivity to humidity may be the result of an electrostatic interaction between the water and the graphene. Of all the gasses comprising air, water is the only one containing a dipole. Thus, simulation of the water/graphene interaction can provide insight into the sensitivity mechanism. A number of studies have previously investigated the effect of the presence of water molecules on the surface of graphene on SiO₂ substrates.^{35–39} Building upon these investigations, ground-state density functional theory calculations for graphene in different configurations of humid environments were performed. The graphene–water system is modelled as single water molecules that are arranged in a monolayer of water above a single-layer graphene sheet with a separation of 3.5 Å. The graphene sheet rests above a layer of SiO₂. The experimentally observed change in conductivity in the graphene suggests that the water molecules dope the graphene layer. We therefore performed density functional calculations on the graphene–water system for different cases: a perfect SiO₂ substrate and an SiO₂ substrate with a well-established surface defect, a Q₃⁰ defect.^{40,41} The distance between the Q₃⁰ silicon atom and the graphene sheet is set to 4.1 Å in our simulations. The surface defect was then incorporated into the simulation for two relevant cases, *i.e.* with and without the monolayer of water molecules. The unit cell of the simulation is shown in Fig. 5a. The red dotted line denotes the cutting plane through which the charge density difference is examined. The Q₃⁰ defect is introduced into the system as illustrated in Fig. 5b. The figure shows a contour map of the charge density difference of the defected system in the absence of a water molecule. Likewise, Fig. 5c shows a contour map of the charge density difference in the presence of the water molecule and the Q₃⁰ defect. When a defect is present in the SiO₂ surface, substantial charge transfer occurs and a dipole moment is formed in the SiO₂ layer. Fig. 5d shows the perfect system (*i.e.* no defect in the SiO₂ is present). In the case of the perfect system, a hydrogen atom is used to passivate the dangling oxygen atomic bond in the substrate. When both the Q₃⁰ defect and the water molecules are present (Fig. 5c), the charge density between the graphene layer and the water molecules becomes significantly different compared to the system

with Q_3^0 defects but without water (Fig. 5b) as well as the perfect system (Fig. 5d). In the calculations, the SiO_2 surface defects give rise to an impurity band, similar to the results of Wehling *et al.*³⁹ The electrostatic dipole moment of the water

molecules may now shift this impurity band, leading to an effective doping and increased conductivity in the graphene layer, which is in line with the experimental observations. However, the simulations reveal that the humidity sensing

Fig. 5 Charge-density difference (CDD) plots for the three simulated systems. The CDD is calculated by subtracting the charge density of the corresponding subsystems from the calculated charge density of the system. (a) Unit cell of graphene on top of SiO₂ with Q₃ defects, with water added on top of the graphene layer. (b) CDD for graphene on top of SiO₂ with Q₃ defects present. No water. (c) CDD for the same system as in (b), but with water added on top of the graphene layer. (d) CDD for graphene on top of defect-free SiO₂, with water added on top of the graphene layer. Note the charge accumulation at the graphene surface in panel (c) where both Q₃ defects and water are present.

effect is due to the graphene layer contacting both the defected SiO₂ layers while being influenced by water. Further, freestanding graphene may not be sensitive to water molecules.³⁸ This is an interesting prediction which suggests that graphene's substrate can effectively functionalize the material to become more sensitive to a specified adsorbent.

In order to benchmark the investigated resistive graphene humidity sensors against a commercial product and other suggested potential nanotechnologies, Fig. 6a shows a comparison with the characterized humidity range of a number of different humidity sensors reported in the literature.^{4,14–16,42,43} The graphene sensor in the present study has been characterized for a larger humidity range than any other experimental device in the literature. Fig. 6b compares the response times of the presented graphene device with that of graphene oxide (GO) and tin oxide (SnO₂) resistive sensors. Note that while both GO and graphene outperform SnO₂, GO appears to be a superior sensor with respect to both response and recovery times. However, this is rather due to limitations in the measurement setup and the general difficulty in determining precise response and recovery times than the graphene sensor itself. Finally, the sensitivity of the graphene humidity sensor was calculated using eqn (1),

$$S = \frac{\Delta R}{R\Delta\%RH} \times 100. \quad (1)$$

Here, S is defined as the percent change in resistance divided by the percent change in relative humidity. Fig. 6c

compares data for different sensor technologies with those of the graphene sensors investigated in this paper, in particular for the relative humidity (%RH) range, response time, recovery time, and sensitivity.^{4,13–18,42,43} It should be noted that the sensitivities reported for the different emerging humidity sensor technologies are not directly comparable and are therefore only indicative. For example, if the sensitivity of our sensor is compared directly as a simple change in resistance relative to the absolute resistance (without considering the humidity range measured), our values are then comparable to those reported by Ghosh.¹⁷ However, without a consistent measurement range, the sensitivities cannot be adequately compared and are therefore simply reported as measured. Further, the comparably small sensitivity of the graphene layer could be due to less defects in the graphene layer. GO in contrast has a large degree of dangling bonds which could contribute to its sensitivity, albeit at the expense of a higher resistance. For example, graphene based pressure sensors have a resistance on the order of 100s of ohms to approximately 1 kΩ. By comparison, the GO sensors have a resistance on the order of 1 to 10 MΩ.¹⁴ This suggests that graphene would be well suited for low power devices. Further, previous reports have explored how the grain size or grain boundary density can affect the transport properties in graphene^{44–47} with higher density leading to enhanced chemical sensing.^{45,46} Thus, tuning the density of the grain boundaries may be considered to further improve the sensitivity. While GO-based sensors seem to be the most viable sensors for resistive,

Fig. 6 (a) Humidity sensors reported in the literature with the characterized humidity ranges. (b) Response and recovery times for the presented graphene device compared with resistive humidity sensors reported in the literature. (c) Comparison of various humidity sensor technologies with respect to reported %RH ranges, response and recovery times, and sensitivities. Note that the HIH-4000 is a commercial sensor used for comparison in all experiments.

capacitive, and piezoresistive sensing of humidity, the graphene-based resistive sensors investigated in this work perform well in comparison with other resistive humidity sensors. However, one further advantage of graphene over GO may be a greater degree of controllability during fabrication. GO is prepared chemically and there is therefore the possibility of the occurrence of chemical impurities during its preparation.

In conclusion, we have demonstrated and characterized resistive graphene humidity sensors with high specificity to other gas constituents present in air. The simulations performed in this work suggest that the sensitivity of the resistance of a graphene patch to water vapor results from the interaction between the water electrostatic dipole moment and the impurity bands in the substrate. This effect in turn leads to doping of the graphene layer, causing increased conductivity as a result of the increased doping. We therefore propose that electrostatic dipole moments play a key role in graphene doping and the related sensing mechanism, in particular since all other molecules studied here were free of electrostatic dipole moments. The graphene sensors show wide range

sensitivity and good response and recovery times with values ranging below one second, competing with graphene oxide based humidity sensors and significantly outperforming previous graphene based humidity sensors. The simplicity of the device design using CVD graphene potentially offers a low cost, scalable technology that is integrable with back-end-of-the-line commercial semiconductor technology.

Methods

Devices consisting of graphene patches were fabricated on p-doped silicon substrates with a 300 nm thick SiO₂ layer. After thermal oxidation to 300 nm of SiO₂, four contact pads were embedded into the substrate. First, 200 nm deep cavities were etched into the SiO₂ layer by reactive ion etching (RIE) using Ar and CHF₃ gas at 200 W and 40 mTorr. Afterwards, 20 nm of titanium were evaporated to act as an adhesion layer, followed by the deposition of 200 nm of gold. The contacts were patterned using a lift-off process with the same self-aligned mask for RIE and metal deposition. The resulting

contacts extended 20 nm above the substrate. This procedure limits the number of processing steps after the graphene transfer, as particularly the lift-off process can damage the graphene. The bond pads on the chips are 100 μm by 100 μm in order to allow sufficient area for the wire bonds. At this point, the wafers were diced into chip size. A layer of graphene was then deposited on the surface of the chip using a CVD graphene wet transfer technique.³² An added advantage of depositing graphene in the final process step before device packaging and characterization is that the risk for damaging and contaminating the graphene by subsequent process steps is reduced. The CVD graphene we used was both grown in house as well as commercially available graphene on copper foils. The graphene in both cases is of comparable quality and a more detailed analysis of the graphene quality is given in the ESI.† A layer of poly(bisphenol A) carbonate (PC) was spin-coated onto the front side of the foil in order to act as a carrier layer.^{50–54} Carbon residues on the backside of the copper foil were removed using an O₂ plasma etch. The copper foil was then etched in ferric chloride (FeCl₃), leaving the graphene/polymer layer floating in the solution. The graphene was then cleaned of Fe ions using 8% HCl by volume and water. Next, the graphene was transferred from the solution to the chip. The chip was subsequently dried on a hot plate at 45 °C for 5 minutes. It was then left in chloroform for about 12 hours in order to remove the polymer carrier layer. The graphene was then patterned using a photoresist mask (SPR 700-1.2) and O₂ plasma for etching of the exposed graphene. After removal of the photoresist in acetone/isopropanol, the chips were wire bonded into chip packages (Fig. 1c) to allow for reliable experiments in various chambers and environments. All experiments are performed at room temperature.

Simulations have been performed using ground-state density functional theory calculations for graphene existing in different configurations of humid environments. The model is comprised of single water molecules arranged in a monolayer on top of the graphene sheet, with 3.5 Å as the distance between the graphene and the monolayer of water molecules. The Kohn–Sham equations have been solved using a plane wave basis set⁵⁵ with a cut-off at 130 Ry and norm-conserving pseudo-potentials as implemented in the Quantum Espresso (QE) simulation package.⁵⁶ The Perdew, Burke and Ernzerhof (PBE) functional⁵⁷ approximation to the exchange–correlation part of the density functional was used. Hamann, Schluter, Chiang and Vanderbilt⁵⁸ (HSCV) norm-conserving pseudo-potentials were used for all the atoms. Calculations of the total energy self-consistent field (SCF) were performed using a 16 × 16 × 1 *k*-point mesh.

Author contribution statement

A. D. S., F. N. and M. C. L. conceived the experiments. A. D. S. performed the experiments and drafted the manuscript. K. E. carried out the simulations, with support from A. D., L. B. and M. R. H. H., A. D. and

K. E. analyzed the output from the simulations and wrote the theory part of the paper. A. C. F. contributed to optimization of the experimental setup. F. F. designed the pulse measurement setup used in the experiments. S. V. contributed device fabrication technology. S. S. performed wire bonding of all devices. S. K. grew the CVD graphene films. A. D. S., F. N., M. Ö. and M. C. L. analyzed the experimental results and all authors co-wrote and reviewed the manuscript.
