## A cyclic trinuclear silver complex for photosynthesis of hydrogen peroxide†

Ri-Qin Xia,  Zhen-Na Liu, Yu-Ying Tang, Xiao Luo, Rong-Jia Wei,  Tao Wu,  Guo-Hong Ning \* and Dan Li \*

The development of metal complexes for photosynthesis of hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>) from pure water and oxygen using solar energy, especially in the absence of any additives (e.g., acid, co-catalysts, and sacrificial agents), is a worthwhile pursuit, yet still remains highly challenging. More importantly, the O<sub>2</sub> evolution from the water oxidation reaction has been impeded by the classic bottleneck, the photon-flux-density problem of sunlight that could be attributed to rarefied solar radiation for a long time. Herein, we reported synthesis of boron dipyrromethene (BODIPY)-based cyclic trinuclear silver complexes (Ag-CTC), and they exhibited strong visible-light absorption ability, a suitable energy bandgap, excellent photochemical properties and efficient charge separation ability. The integration of BODIPY motifs as oxygen reduction reaction sites and silver ions as water oxidation reaction sites allows Ag-CTC to photosynthesize H<sub>2</sub>O<sub>2</sub> either from pure water or from sea water in the absence of any additives with a high H<sub>2</sub>O<sub>2</sub> production rate of 183.7 and 192.3 μM h<sup>-1</sup>, which is higher than that of other reported metal-based photocatalysts. The photocatalytic mechanism was systematically and ambiguously investigated by various experimental analyses and density functional theory (DFT) calculations. Our work represents an important breakthrough in developing a new Ag photocatalyst for the transformation of O<sub>2</sub> into H<sub>2</sub>O<sub>2</sub> and H<sub>2</sub>O into H<sub>2</sub>O<sub>2</sub>.

## Introduction

Hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>), an environment-friendly oxidant and a clean fuel is widely used in medical disinfection, water treatment and chemical synthesis,<sup>1–10</sup> with an annual demand of 5.7 million tons by 2027.<sup>11</sup> So far, the anthraquinone oxidation process is still the most used approach for H<sub>2</sub>O<sub>2</sub> production in industry; however, it requires expensive palladium catalysts and a large amount of harmful organic solvent and consumes lots of energy.<sup>12</sup> Therefore, it is a worthwhile pursuit to develop green and efficient catalysts, especially solar photocatalysts, for H<sub>2</sub>O<sub>2</sub> production from water and oxygen due to its potential for solving global energy shortage and ecological issues.

Artificial photosynthesis of H<sub>2</sub>O<sub>2</sub> using metal complexes (MCs) requires several processes including light absorption, charge-separation, the water oxidation reaction (WOR) and the oxygen reduction reaction (ORR). Currently, the ORR half-reaction has been predominantly investigated for photosynthesis of H<sub>2</sub>O<sub>2</sub>; however, the WOR half-reaction is not sufficiently exploited,<sup>13–17</sup> which severely hindered practical application. This because the WOR process suffers from

sluggish kinetics, the so called “photo-flux-density problem of sunlight”,<sup>18,19</sup> especially for the photocatalytic four-electron (4e<sup>-</sup>) oxygen evolution reaction (OER). Typically, the generation of O<sub>2</sub> photo-catalysis by MCs takes seconds, which is far longer than the timescale for hole generation and migration.<sup>18,19</sup> During this long period, the photocatalyst would undergo undesired decomposition or transformation, leading to a loss of catalytic activity. Therefore, it is a worthwhile pursuit to develop MCs that are capable of photo-catalyzing both the ORR and WOR, yet it still remains highly challenging.

Conventionally, to bypass the WOR issues, hybrid catalytic systems involving two or more different components are designed (Scheme 1a).<sup>11,12,20–22</sup> For instance, Ru or Cu complexes as photocatalysts or photosensitizers for the 2e<sup>-</sup> ORR, and Co/Ir complexes or semiconductors (i.e., WO<sub>3</sub> or BiVO<sub>4</sub>) as water oxidation catalysts (WOCs) are combined for producing H<sub>2</sub>O<sub>2</sub>.<sup>11,23–28</sup> Moreover, the addition of sacrificial agents, a superoxide anion radical (O<sub>2</sub><sup>•-</sup>) stabilizer (i.e., Sc(NO<sub>3</sub>)<sub>3</sub>) and a proton source (e.g., H<sub>2</sub>SO<sub>4</sub> or HClO<sub>4</sub>) is required in these homogeneous catalytic systems. Thus, these processes not only produce by-products and harmful waste, but also require additional purification steps. Furthermore, low visible-light absorption ability of reported MCs, decomposition of H<sub>2</sub>O<sub>2</sub> triggered by MCs, and the unsatisfactory H<sub>2</sub>O<sub>2</sub> production performance also remains unresolved problems in this field.

Scheme 1 Schematic illustration of (a) conventional metal-based hybrid catalytic systems and (b) a Ag-CTC complex in this work for photosynthesis of H<sub>2</sub>O<sub>2</sub>. (ORC and WOC mean the oxygen reduction catalyst and water oxidation catalyst).

More importantly, these photocatalytic systems did not address the WOR bottleneck.

Recently, great efforts have been put into developing transition MCs with strong visible-light absorption, which can be used in photocatalytic oxidation, and hydrogen evolution from water.<sup>29–32</sup> For instance, the incorporation of boron dipyrromethene (BODIPY) into a cyclic trinuclear copper(i) complex (Cu-CTC) has significantly improved its visible-light absorption, leading to light-induced O<sub>2</sub><sup>•−</sup> generation from molecular oxygen (O<sub>2</sub>). Since O<sub>2</sub><sup>•−</sup> is involved in one of the reaction pathways for photosynthesis of H<sub>2</sub>O<sub>2</sub> (see eqn (1)–(5)), we hypothesize that BODIPY-based CTCs might be promising photocatalysts for H<sub>2</sub>O<sub>2</sub> production and address the above-mentioned issues.

Herein, we rationally designed BODIPY-based Ag-CTC (Ag<sub>3</sub>L<sub>3</sub>, **1**) and Cu-CTC (Cu<sub>3</sub>L<sub>3</sub>, **2**) by complexation between a BODIPY-based pyrazolyl ligand (HL) and silver benzoate (PhCOOAg) or Cu(NO<sub>3</sub>)<sub>2</sub>, respectively (Scheme 1b). For comparison, Ag<sub>3</sub>L<sub>3</sub><sup>1</sup> (**3**, HL<sup>1</sup> represents 3,5-bis(trifluoromethyl)-1*H*-pyrazole) as a reference compound was also synthesized.<sup>33</sup> The incorporation of the BODIPY motif remarkably improved the photophysical properties of **1** and **2**, and they both featured high molar absorptivity ( $\epsilon = \sim 7.4$  and  $7.9 \times 10^4 \text{ M}^{-1} \text{ cm}^{-1}$ ), and good photo-induced charge-separation efficiency in the visible-light range. Under light irradiation, Ag-CTC **1** as a heterogenous photocatalyst delivered a high H<sub>2</sub>O<sub>2</sub> production rate of 183.7  $\mu\text{M h}^{-1}$  in the absence of a co-catalyst, sacrificial agents and acid, and it performed better than HL, Cu-CTC **2** and reference compound **3**. Notably, to the best of our knowledge, Ag-CTC **1** is

the best metal complex-based photocatalyst for H<sub>2</sub>O<sub>2</sub> production to date. The mechanistic studies further revealed that Ag-CTC **1** can generate H<sub>2</sub>O<sub>2</sub> through a stepwise e<sup>−</sup> ORR pathway (*i.e.*, O<sub>2</sub> → O<sub>2</sub><sup>•−</sup> → H<sub>2</sub>O<sub>2</sub>), and we unexpectedly found that the holes generated after visible-light irradiation can be used to perform the oxygen evolution reaction (OER). The 4e<sup>−</sup> WOR occurred at the silver center. Our work, for the first time, has demonstrated that molecular metal complexes composed of oxygen reduction and oxidation centers can be used in the full reaction photosynthesis of H<sub>2</sub>O<sub>2</sub> without sacrificial agents.

## Results and discussion

### Synthesis and characterization

The BODIPY-based pyrazolyl ligand (HL) was prepared according to our previous work.<sup>29</sup> The mixture of HL and PhCOOAg in anhydrous THF solution was stirred for 24 hours in the dark at room temperature (rt) to give compound **1** as an orange powder (Scheme S1†). The structure of **1** was characterized by using <sup>1</sup>H, <sup>19</sup>F, and <sup>13</sup>C NMR spectra (Fig. S1–S3†). The disappearance of the N–H signal of ligand HL at 13.81 ppm suggested the deprotonation of HL and formation of Ag–N bonds. The <sup>19</sup>F NMR spectra of **1** and HL revealed that they both display one <sup>19</sup>F peak located at −141.89 and −141.66 ppm, respectively, further proving the purity of **1**. The X-ray photoelectron spectroscopy (XPS) measurement of **1** showed intensely sharp and symmetrical Ag(i) 2d<sub>3/2</sub> and 2d<sub>5/2</sub> peaks at 374.09 and 368.10 eV, respectively (Fig. S5†). Energy-dispersive X-ray spectroscopy (EDS) elemental mapping confirmed that Ag, C, N, B, and F elements were evenly distributed in **1** (Fig. S6†). The orange crystals suitable for single-crystal X-ray diffraction (SXRD) analysis can be obtained with a yield of 13.7% by the solvothermal synthesis method.<sup>34</sup>

As shown in Fig. 1, **1** was crystalized in the *Ia* $\bar{3}$  cubic space group, exhibiting nine-membered Ag<sub>3</sub>N<sub>6</sub> units with a distorted planar structure (Fig. 1a). The dihedral angle between the Ag<sub>3</sub>N<sub>6</sub> plane and the BODIPY unit is  $\sim 31^\circ$ , leading to a propeller-shaped structure with three blades (Fig. 1a). In addition, two Ag-CTCs tightly stacked with each other to form a dimer with an interdimer Ag⋯Ag distance of 3.75 Å (Fig. 1b), revealing strong Ag–Ag interactions. Reference compound Cu-CTC **2** (ref. 29) and Ag<sub>3</sub>L<sub>3</sub><sup>1</sup> **3** (ref. 35 and 36) were synthesized for comparison and their crystal structures are shown in Fig. 1c and d, respectively. They both exhibited similar nine-membered planar configurations. Furthermore, thermo-gravimetric analysis (TGA) of **1** revealed that it started to decompose at 260 °C (Fig. S9†). The phase purity of **1** was confirmed by powder X-ray diffraction

Fig. 1 Crystal structures of (a) Ag-CTC 1, (c) Cu-CTC 2 and (d)  $\text{Ag}_3\text{L}_{13}$  3, exhibiting one CTC unit structure. (b) Side view of tightly packed 1 showing an interdimer Ag...Ag distance of 3.75 Å (ball-stick model) (color codes: C, wheat; N, blue; Cu, orange; Ag, silver; B, light pink; and F, light green).

(PXRD) (Fig. S10<sup>†</sup>). The water contact angles of **HL**, **1**, **2** and **3** are all larger than  $110^\circ$ , suggesting that they are all hydrophobic (Fig. S13<sup>†</sup>).

### Optics and electrochemistry

The UV-vis absorption spectra of **1** exhibited strong adsorption at 497 nm with an exceptionally high molar extinction coefficient ( $\epsilon$ ) of  $74\,353\text{ M}^{-1}\text{ cm}^{-1}$  (Fig. S16 and S17<sup>†</sup>). This value is similar to that of compound **2** ( $\epsilon = 78\,515\text{ M}^{-1}\text{ cm}^{-1}$ ) and approximately 5.17 times higher than that of **HL** ( $\epsilon = 14\,379\text{ M}^{-1}\text{ cm}^{-1}$ ).<sup>13</sup> In addition, the solid-state UV-vis diffuse reflection spectra of **HL**, **1**, **2** and **3** were obtained to study light absorption ability. Specifically, **2** exhibited the widest absorption range (*i.e.*, 200–800 nm), while **3** showed the narrowest absorption range (*i.e.* 200–400 nm) (Fig. 2a). **HL** and **1** delivered similar absorption edges at  $\sim 600$  nm. These results suggested that the incorporation of BODIPY units remarkably improved visible-light harvesting ability of CTCs. The optical bandgaps ( $E_g$ ) of **HL**, **1**, **2** and **3** were estimated to be 1.97, 2.16, 1.76 and 2.94 eV, respectively by using the Tauc plot (Fig. 2b). The flat band potentials of **HL**, **1**, **2** and **3** were determined to be  $-1.38$ ,  $-0.80$ ,  $-1.33$  and  $-1.47$  eV *vs.* NHE at pH = 7 through the Mott-Schottky experiments,<sup>37</sup> respectively (Fig. S18–S21<sup>†</sup>), which were equal to their conduction band (CB) potentials. Combining the Mott-Schottky experiments and optical bandgap data, valence band ( $V_B$ ) potentials of **HL**, **1**, **2** and **3** were calculated to be 0.59, 1.36, 0.43 and 1.47 eV *vs.* NHE at pH = 7 (Fig. 2c). Since the reduction potentials of  $\text{O}_2(\text{g})/\text{O}_2^{\cdot-}$  and  $\text{O}_2(\text{g})/\text{H}_2\text{O}_2$  are known to be  $-0.35$  and  $0.28$  V *vs.* NHE at pH = 7,<sup>38</sup> they are thermodynamically suitable for photocatalytic reduction of  $\text{O}_2$  to give  $\text{H}_2\text{O}_2$ . In addition, the oxidation potential of  $\text{H}_2\text{O}/\text{O}_2$  is 0.82 V *vs.* NHE at pH = 7;<sup>39</sup> thus, compounds **1** and **3** are

thermodynamically suitable for photocatalytic oxidation of water to produce  $\text{O}_2$  and protons.

To further probe the optical and photo-electrochemical properties of **HL**, **1**, **2** and **3**, photoluminescence (PL) spectra were obtained, and electrochemical impedance spectroscopy (EIS) and transient photocurrent measurements were performed. The steady-state PL spectra of **HL**, **1**, **2** and **3** in the suspended-state were obtained (Fig. 2d). **HL**, **1** and **2** showed bright green emission with maximum emission peak ( $\lambda_{\text{em}}$ ) positions at 514 nm, while the emission intensity of **3** was very weak (Fig. S24–S28<sup>†</sup>). Compounds **1** and **2** exhibited similar emission intensity, much lower than that of **HL**, suggesting that **1** and **2** possessed the highest separation efficiency of photo-induced electron-hole pairs and the presence of electron transfer.<sup>40</sup> Moreover, **2** possessed the highest photocurrent density, while the transient photocurrent density of **1** was larger than that of **HL** and **3** under visible-light irradiation, implying an effective spatial separation of photogenerated charge carriers in **1** and **2** (Fig. 2e). The EIS spectra of **HL**, **1**, **2** and **3** exhibited semicircles; meanwhile **1** and **2** delivered the lowest charge transfer resistance (Fig. 2f), indicating the highest charge-separation efficiency in **1** and **2**.

### Photosynthesis of $\text{H}_2\text{O}_2$

The visible-light photosynthesis of  $\text{H}_2\text{O}_2$  was initially tried in pure water under an  $\text{O}_2$  atmosphere and the yield of  $\text{H}_2\text{O}_2$  was determined by iodometric titration.<sup>41</sup> The production rate of  $\text{H}_2\text{O}_2$  with different amounts of photocatalyst **1** (*i.e.* 1, 2, 3, 4 and 5 mg) in 5 mL pure water was measured. It was found that 4 mg of **1** furnished the highest  $\text{H}_2\text{O}_2$  production rate of  $229.7\ \mu\text{mol g}^{-1}\text{ h}^{-1}$  (Fig. S33<sup>†</sup>). Fig. 3a shows the photocatalytic performances of **HL**, **1**, **2** and **3**, and a linear relationship between  $\text{H}_2\text{O}_2$  production and irradiation time was observed under optimal conditions. With compound **1**, the concentration of  $\text{H}_2\text{O}_2$  gradually increased to  $918.5\ \mu\text{M}$  after 5 hours, and the production rate was estimated to be  $183.7\ \mu\text{M h}^{-1}$  (Fig. 3a). In sharp contrast, when **HL**, **2** and **3** were employed as photocatalysts, no  $\text{H}_2\text{O}_2$  was detected (Fig. 3a). Notably, although Cu-CTC **2** exhibited better photoinduced charge separation efficiency than Ag-CTC **1**, **2** was not able to produce  $\text{H}_2\text{O}_2$  under light irradiation. This is because  $\text{H}_2\text{O}_2$  decomposition is catalyzed by **2** (Fig. S35<sup>†</sup>), which has also observed for other reported Cu-CTC complexes.<sup>42</sup> In addition, the unsuitable bandgaps of **HL**, and **2** for the  $4e^-$  WOR also hampered the photosynthesis of  $\text{H}_2\text{O}_2$ . Moreover, although Ag-CTC **3** had a suitable optic bandgap, the low light absorption ability impeded the photo-production of  $\text{H}_2\text{O}_2$ .

The long-term photostability of catalysts is practically important; thus, the continuous photosynthesis of  $\text{H}_2\text{O}_2$  was conducted. In a continuous experiment (Fig. 3b), the  $\text{H}_2\text{O}_2$  production rate leveled off after about 15 h using **1**. The amount of  $\text{H}_2\text{O}_2$  produced under pure  $\text{O}_2$  (99%) was 6.7 times greater than that in air, and no  $\text{H}_2\text{O}_2$  was detected under a continuous Ar atmosphere, suggesting that  $\text{O}_2$  is essential for  $\text{H}_2\text{O}_2$  production (Fig. 3c and see the ESI<sup>†</sup> for details). The apparent quantum yield (AQY) of **1** was measured determined to be

(f) Nyquist plots of HL, 1, 2 and 3.

Fig. 3 (a) Time course of photocatalytic  $\text{H}_2\text{O}_2$  production for HL, 1, 2 and 3 irradiated with a 300 W xenon lamp fitted with a  $\lambda > 420$  nm filter. (b) Long-term photocatalytic  $\text{H}_2\text{O}_2$  production of 1. (c) Photocatalytic  $\text{H}_2\text{O}_2$  production activities of 1 under different gas atmospheres. (d) Comparison of the  $\text{H}_2\text{O}_2$  production rate with representative metal-based photocatalysts. The error bars denote  $\pm$ s.d. of the mean for three independent experiments in (a) and (c).

0.039%, 0.043%, 0.035%, 0.040% and 0.042% at 420, 450, 485, 520 and 535 nm, respectively (Fig. S38<sup>†</sup>), suggesting a visible-light promoted  $\text{H}_2\text{O}_2$  production process. Compared to pure water, sea water is the most earth-abundant resource. Thus,

photosynthesis of  $\text{H}_2\text{O}_2$  from sea water is highly desired, yet is a significant challenge due to the complex composition and high salt concentration of seawater. Interestingly, 1 demonstrated an even higher  $\text{H}_2\text{O}_2$  photo-production rate of  $192.3 \mu\text{M h}^{-1}$  using seawater (Fig. S40 and S41<sup>†</sup>). Notably, 1 delivered the highest  $\text{H}_2\text{O}_2$  production rate among reported metal-based photocatalysts (Fig. 3d).<sup>23,25,43–47</sup> These results indicate that 1 is a promising photocatalyst for  $\text{H}_2\text{O}_2$  production. However, with the increase in photo-generated holes and concentration of  $\text{H}_2\text{O}_2$ , the photo-catalytic performance decreased after 15 h of photo-irradiation, and the crystallinity of 1 declined as confirmed by PXRD analysis (Fig. S42<sup>†</sup>). These results suggested the moderate stability and durability of complex 1 during photosynthesis of  $\text{H}_2\text{O}_2$ . Nevertheless, our work presented a rare example of a Ag complex for photo-catalyzing both the ORR and OER.

To reveal the photocatalytic mechanism, several control experiments were conducted. Firstly, the  $\text{H}_2\text{O}_2$  production rate increased to  $237.8 \mu\text{M h}^{-1}$  with *tert*-butanol (TBA) as the sacrificial agent. The enhancement of the  $\text{H}_2\text{O}_2$  production rate in the presence of TBA as electron donors indicated that  $\cdot\text{OH}$  did not participate in the  $\text{H}_2\text{O}_2$  production reaction (Fig. 4a).<sup>48</sup> Secondly, the addition of  $\text{AgNO}_3$  as electron acceptors significantly decreased the  $\text{H}_2\text{O}_2$  production rate to  $30.5 \mu\text{M h}^{-1}$ , indicating that photogenerated electrons played a vital role in the photocatalytic ORR. Thirdly, in the presence of  $\text{La}_2\text{O}_3$ ,  $\text{NaIO}_3$  and 1 in pure water,  $\text{O}_2$  was detected and the production rate was estimated to be  $81.8 \mu\text{mol g}^{-1} \text{h}^{-1}$  after 5 h of photo-irradiation (Table S3 and Fig. S44, S45<sup>†</sup>). This observation

Fig. 4 (a) Photocatalytic H<sub>2</sub>O<sub>2</sub> production activities of **1** with the addition of different sacrificial agents (the unit is μM h<sup>-1</sup>). The error bars denote ±s.d. of the mean for three independent experiments. (b) EPR trapping experiments in the presence of DMPO before (gray line) and after (light red line) light irradiation. (c) *In situ* DRIFT spectra of **1** during H<sub>2</sub>O<sub>2</sub> photosynthesis (the time interval is 10 min). (d) Isotopic <sup>18</sup>O<sub>2</sub> labeling experiments.

suggests that Ag-CTC **1** is able to directly photo-produce O<sub>2</sub> from water through the 4e<sup>-</sup> OER. To further prove that O<sub>2</sub> was photo-generated from water, the H<sub>2</sub><sup>18</sup>O isotopic labeling experiment was conducted.<sup>49,50</sup> As shown in Fig. S46,† in the presence of <sup>16</sup>O<sub>2</sub> and H<sub>2</sub><sup>18</sup>O, the reaction mixture was irradiated after 12 hours. Afterward, the resulting solution was decomposed by MnO<sub>2</sub>, and <sup>18</sup>O<sub>2</sub> was observed by mass spectroscopy, indicating that H<sub>2</sub><sup>18</sup>O participated in the OER to generate <sup>18</sup>O<sub>2</sub>, and the generated <sup>18</sup>O<sub>2</sub> was further captured in the ORR to convert H<sub>2</sub><sup>18</sup>O<sub>2</sub>. Finally, the addition of *p*-benzoquinone (BQ) as an O<sub>2</sub>•<sup>-</sup> scavenger<sup>51</sup> completely inhibited H<sub>2</sub>O<sub>2</sub> production (Fig. 4a), suggesting that O<sub>2</sub>•<sup>-</sup> was required during the photosynthesis of H<sub>2</sub>O<sub>2</sub>. These results are consistent with the observed optical properties of **1**. For instance, the CB and VB of **1** also suggested that the 2e<sup>-</sup> ORR (*i.e.*, O<sub>2</sub> to H<sub>2</sub>O<sub>2</sub>) and 4e<sup>-</sup> WOR (*i.e.*, H<sub>2</sub>O to O<sub>2</sub>) are thermodynamically possible, while e<sup>-</sup> (*i.e.*, H<sub>2</sub>O to •OH) and 2e<sup>-</sup> WOR (*i.e.*, H<sub>2</sub>O to H<sub>2</sub>O<sub>2</sub>) are thermodynamically prohibited.

To further study the reaction pathway of H<sub>2</sub>O<sub>2</sub> production by Ag-CTC **1**, the average electron transfer number of Ag-CTC **1** was determined to be 2.00 based on the results of rotating disc electrode (RDE) studies conducted on O<sub>2</sub> reduction processes (Fig. S47†), which showed that Ag-CTC **1** could reduce O<sub>2</sub> to H<sub>2</sub>O<sub>2</sub> using the direct two-electron reduction pathway. Meanwhile, 5,5-dimethyl-1-pyrroline *N*-oxide (DMPO) was employed as the radical trapping agent for detecting O<sub>2</sub>•<sup>-</sup> in electron paramagnetic resonance (EPR) measurements. No noticeable signals can be found under dark conditions, while the characteristic signals of DMPO-O<sub>2</sub>•<sup>-</sup> appeared after light irradiation (Fig. 4b).<sup>52</sup> Such results further supported the generation of O<sub>2</sub>•<sup>-</sup> through the one-electron reduction of O<sub>2</sub>. In addition, the adsorbed intermediates on **1** during the H<sub>2</sub>O<sub>2</sub> production process were revealed by *in situ* diffuse reflectance infrared

Fourier transform spectroscopy (DRIFTS). As shown in Fig. 4c, the O–O stretching signals for O<sub>2</sub> as well as O<sub>2</sub>•<sup>-</sup>\*, •OOH\*, and HOOH\* (\* denoted as surface-adsorbed) were found at 954, 1160, 1211 and 1379 cm<sup>-1</sup>, respectively.<sup>53–55</sup> Moreover, isotopic labeling experiments using <sup>18</sup>O<sub>2</sub> were also performed. The percentage of <sup>18</sup>O<sub>2</sub> detected by mass spectroscopy increased from 0% to 88.2% over 5 h and further decreased to 75.3% after 10 h (Fig. 4d), suggesting that the <sup>16</sup>O<sub>2</sub> generated by the OER would be captured in the ORR and converted into H<sub>2</sub><sup>16</sup>O<sub>2</sub>. Such results are consistent with the H<sub>2</sub><sup>18</sup>O isotopic labeling experiment, and reveal that the photosynthesis of H<sub>2</sub>O<sub>2</sub> using Ag-CTC **1** involves stepwise ORR (*i.e.*, O<sub>2</sub> → O<sub>2</sub>•<sup>-</sup> → H<sub>2</sub>O<sub>2</sub>)<sup>56</sup> and the 4e<sup>-</sup> OER process (*i.e.*, H<sub>2</sub>O → O<sub>2</sub>).

### Theoretical studies

Density functional theory (DFT) calculations were conducted by Gaussian 09E (ref. 57) software to further study the reaction mechanism. The electrostatic potential (ESP)<sup>58,59</sup> distribution is used to describe the charge distribution on the surface of molecule **1** (Fig. S53†). The electrostatic potential value surrounding the BODIPY moiety has a negative value, while the nine-membered Ag<sub>3</sub>N<sub>6</sub> unit exhibits a positive value, suggesting that the BODIPY region has a higher affinity for electrons and is more electrophilic compared to the nine-membered Ag<sub>3</sub>N<sub>6</sub> unit.<sup>60</sup> Thus, the electrons prefer to be transferred from the Ag<sub>3</sub>N<sub>6</sub> unit to the BODIPY motifs.<sup>1</sup> In addition, the cyclic voltammetry (CV) test was performed to study their redox potentials. The CV curve of **1** exhibited two reversible redox processes with the peak potential at approximately -1.65 and -1.26 V (*vs.* Fc<sup>+/0</sup>), respectively, which can be assigned to the redox couple of Ag<sup>II</sup>/Ag<sup>I</sup>, and the BODIPY ligands (Fig. S52†). The more negative reduction potential of the Ag center compared to that of BODIPY ligands further suggests that the electron transfer process from the Ag to BODIPY unit is thermodynamic feasible.<sup>61</sup> Moreover, as shown in Fig. 5a, the electrons were primarily localized at the BODIPY units either in the highest occupied or lowest unoccupied molecular orbital (HOMO or LUMO). According to the time-dependent density-functional theory (TDDFT) calculation results, it is indicated that BODIPY units contribute more in the transition from the ground state (S<sub>0</sub>) to the first 10 S<sub>n</sub> states with an *f* larger than 0.01 (Table S4†). This further confirms that for **1**, the electrons are mainly localized on the BODIPY units. Based on the above discussion, we propose that the mechanism for H<sub>2</sub>O<sub>2</sub> production involves the ORR occurring on BODIPY, while the WOR takes place on the Ag<sub>3</sub>N<sub>6</sub> unit.

For the ORR process, a plausible reaction mechanism is proposed in Fig. 5b. The adsorption energy (Δ*E*<sub>ad</sub>) of O<sub>2</sub> in the BODIPY region of **1** and **2** was calculated to be 0.2469 and 0.2709 eV, respectively (Fig. S55–S58 and Table S5†), suggesting that the adsorption of O<sub>2</sub> either on **1** or **2** is thermodynamically infeasible. Nevertheless, the more negative Δ*E*<sub>ad</sub> value of **1** compared to **2** indicates that O<sub>2</sub> prefers to be adsorbed on **1** (Fig. 5c). It is well known that the formation of the •OOH intermediate is a crucial step during the synthesis of H<sub>2</sub>O<sub>2</sub>,<sup>55,62,63</sup> thus the Gibbs free energy of the •OOH intermediate (Δ*G*<sub>OOH\*</sub>)

Fig. 5 (a) HOMO and (b) LUMO of **1** in the optimized structure (iso-value = 0.05 a.u.). (c) Calculated free energy for H<sub>2</sub>O<sub>2</sub> formation from O<sub>2</sub> at the DFT-D3 (BJ) level of theory. (d) The proposed photocatalytic mechanism for H<sub>2</sub>O<sub>2</sub> synthesis in the presence of photocatalyst **1** (\* denoted as surface-adsorbed).

adsorbed in the BODIPY region for **1** (*i.e.*, 0.1502 eV) and **2** (*i.e.*, 0.2664 eV) is assessed and compared (Fig. 5c). The more negative value of  $\Delta G_{\text{OOH}^*}$  for **1** suggests that **1** is more active for 'OOH intermediate production. Furthermore, the negative value of  $\Delta G_{\text{H}_2\text{O}_2}$  (−0.8719 eV) produced on the BODIPY unit for **1** (Fig. 5c) implies that the production of H<sub>2</sub>O<sub>2</sub> from the 'OOH intermediate is thermodynamically favored.

For the 4e<sup>−</sup> WOR process, two H<sub>2</sub>O molecules are required to be adsorbed on the surface of the catalysts to produce one O<sub>2</sub>. Based on the above-mentioned results, the WOR possibly takes place on the Ag<sub>3</sub>N<sub>6</sub> unit of **1**.<sup>64</sup> The  $\Delta E_{\text{ad}}$  of the two H<sub>2</sub>O molecules on the Ag<sub>3</sub>N<sub>6</sub> active site of **1** was also calculated to be −0.3806 eV (Fig. S59 and S60†), further evidencing that the adsorption of H<sub>2</sub>O on the Ag<sub>3</sub>N<sub>6</sub> unit of **1** is thermodynamically favored. We calculated the energy path for water oxidation into oxygen. Based on the experimental results and calculation, a possible mechanism is proposed (Fig. 5d): initially, O<sub>2</sub> is adsorbed on the BODIPY sites. After light irradiation, photo-induced electrons are produced at the BODIPY site, and then O<sub>2</sub> obtains the electron and proton to generate the 'OOH intermediate. Afterward, 'OOH further obtains the electron and proton to produce H<sub>2</sub>O<sub>2</sub>. Meanwhile, two H<sub>2</sub>O molecules can be adsorbed on the Ag<sub>3</sub>N<sub>6</sub> site, and then photoinduced holes obtain electrons from H<sub>2</sub>O to produce O<sub>2</sub> and protons.

## Conclusions

In summary, we have prepared BODIPY decorated Ag-CTC **1**, and it features a suitable energy bandgap, strong visible-light absorption, excellent photochemical properties and efficient charge separation ability. Owing to these merits, complex **1** can be used as a photocatalyst for producing H<sub>2</sub>O<sub>2</sub> either from pure water or from sea water with high photocatalytic activities (183.7 and 192.3 μM h<sup>−1</sup>) in the absence of any additives (*e.g.*, acid, co-

catalysts, and sacrificial agents). The photocatalytic performance is attributed to the prominently enhanced two-electron ORR by forming endoperoxide at the BODIPY unit and highly concentrated holes at the Ag<sub>3</sub>N<sub>6</sub> site. The generated O<sub>2</sub> from the OER is subsequently consumed by the ORR, thereby boosting overall reaction kinetics. The photocatalytic mechanism was systematically investigated by various experimental analyses and DFT calculations. Our studies demonstrated that the integration of organic chromophores as ORR sites and silver centers as OER sites is a new approach for design of efficient metal-based photocatalysts for H<sub>2</sub>O<sub>2</sub> production using solar energy.

## Data availability

The data supporting this article have been included as part of the ESI.† Crystallographic data for complex **1** has been deposited at the CCDC (DOI: <https://doi.org/10.5517/ccdc.csd.cc2gqh2s>) and can be obtained from <https://www.ccdc.cam.ac.uk>.

## Author contributions

G.-H. N., and D. L. designed the research; R.-Q. X. conducted the experiments and data analysis; R.-Q. X. contributed to data analysis and theoretical calculation; R.-Q. X., G.-H. N., and D. L. co-wrote the manuscript. All authors read and commented on the manuscript.

## Conflicts of interest

The authors declare no conflict of interest.

## Acknowledgements

G.-H. N. is thankful for the financial support from the Guangzhou Science and Technology Project (202201020038). This project was supported financially by the National Natural Science Foundation of China (No. 22371091, 21975104, 21731002, 22150004 and 92261205) and the Guangdong Major Project of Basic and Applied Research (No. 2019B030302009). R.-J. W. is thankful to the Open Fund of Guangdong Provincial Key Laboratory of Functional Supramolecular Coordination Materials and Applications (No. 2020B121201005).
