# Thermal transport across copper–water interfaces according to deep potential molecular dynamics†

Zhiqiang Li,<sup>a</sup> Xiaoyu Tan,<sup>b</sup> Zhiwei Fu,<sup>bc</sup> Linhua Liu<sup>id</sup>\*<sup>ab</sup> and Jia-Yue Yang<sup>id</sup>\*<sup>ab</sup>

Nanoscale thermal transport at solid–liquid interfaces plays an essential role in many engineering fields. This work performs deep potential molecular dynamics (DPMD) simulations to investigate thermal transport across copper–water interfaces. Unlike traditional classical molecular dynamics (CMD) simulations, we independently train a deep learning potential (DLP) based on density functional theory (DFT) calculations and demonstrated its high computational efficiency and accuracy. The trained DLP predicts radial distribution functions (RDFs), vibrational densities of states (VDOS), density curves, and thermal conductivity of water confined in the nanochannel at a DFT accuracy. The thermal conductivity decreases slightly with an increase in the channel height, while the influence of the cross-sectional area is negligible. Moreover, the predicted interfacial thermal conductance (ITC) across the copper–water interface by DPMD is  $2.505 \times 10^8 \text{ W m}^{-2} \text{ K}^{-1}$ , the same order of magnitude as the CMD and experimental results but with a high computational accuracy. This work seeks to simulate the thermal transport properties of solid–liquid interfaces with DFT accuracy at large-system and long-time scales.

## 1. Introduction

Thermal transport at solid–liquid interfaces is a crucial phenomenon that occurs widely in the fields of device cooling,<sup>1–3</sup> solar-driven interfacial evaporation,<sup>4</sup> photothermal cancer therapy<sup>5</sup> and laser-induced drug release.<sup>6</sup> Hindered by experimental equipment and the environment, it is extremely difficult to accurately measure the thermal physical properties at the solid–liquid interface when the characteristic length is reduced to the nanoscale.

Classical molecular dynamics (CMD), as a powerful tool to capture atoms' motion trajectories, has been widely applied to simulate nanoscale thermal transport. Ohara and Torii<sup>7</sup> performed CMD simulations to study the shear behavior of liquid water between two solid walls and found that the types of solid surfaces played a critical role in the interfacial thermal transport. Ueki *et al.*<sup>8</sup> investigated the instantaneous interfacial thermal resistance using CMD when the nanoscale water

droplet cools down and freezes. Furthermore, Yu *et al.*<sup>9</sup> performed CMD simulations to study the heat transport through the solid–liquid interface and revealed the direction of energy transport during the evaporation process. Frank *et al.*<sup>10</sup> studied the influence of surface irregularities and imperfections on the interfacial thermal resistance using CMD. A mathematical optimization method of the grooved nanostructured surface design was also used to enhance heat transfer at the solid–liquid interface.<sup>11</sup> Guo *et al.*<sup>12</sup> investigated the interfacial heat transfer between parallel plates and a thin layer of liquid argon with the empirical Lennard–Jones (LJ) potential. Heat flux and temperature drop were calculated in the channel, and then the thermal resistance was evaluated. Though CMD can simulate a solid–liquid system consisting of a large number of atoms, its accuracy suffers from the empirical potential, especially under extreme conditions (high temperature and high pressure). By contrast, *ab initio* molecular dynamics (AIMD) provides a framework for on-the-fly construction of a potential energy surface (PES) using density functional theory (DFT) calculations and has become a powerful tool to investigate the dynamical properties of solid–liquid interfaces.<sup>13,14</sup> However, the high computational cost limits the use of AIMD to the time scale of  $\sim 10$  ps and hundreds of atoms, thus limiting its application in solid–liquid interfaces.

Machine learning potentials (MLPs) combine the high efficiency of CMD with the accuracy of first-principles, and provide a paradigm for accurate simulation of large systems. MLPs have recently been applied to predict the thermal properties,<sup>15–18</sup> optical properties,<sup>19</sup> chemical reactions,<sup>20–22</sup> and phase diagrams<sup>23,24</sup> of crystalline solids or liquids, and demonstrated a greatly

improved computational efficiency over AIMD. Zuo *et al.*<sup>25</sup> performed a comprehensive evaluation of machine learning interatomic potentials (IAPs) and provided a benchmark for common MLPs. Xie *et al.*<sup>26</sup> explored the accuracy/performance tradeoff of different MLPs and the deep learning potentials (DLP) excelled in computational efficiency due to its reduced manual input hyper-parameterization and Graphics Processing Unit (GPU) acceleration. Applications of DLPs to the solid-liquid interface include the proton transport at TiO<sub>2</sub>-water interfaces,<sup>27</sup> the profiles and migration of the Pd-Si solid-liquid interface,<sup>28</sup> and the solid-liquid phase transition of silicon.<sup>29</sup> Recent calculations reported the structural and thermodynamic properties of the liquid-vapor interface using neural-network molecular dynamics.<sup>30,31</sup> To the best of our knowledge, there have been no significant reports of research on the solid-liquid interfacial heat transfer with MLPs. MLPs have great potential for breaking the barrier of incompatible between computational accuracy and speed in the study of heat transfer at the solid-liquid interface. Hence, it is important to improve the applicability of MLPs to solid-liquid interfacial heat transfer, especially for the training process of MLPs and subsequent applications. In this work, we build a nano-channel model consisting of copper, liquid water and copper-water interface, develop a DLP trained on DFT calculations, and apply deep potential molecular dynamics (DPMD) to simulate the thermal transport across the copper-water interface. The DLP is trained by a large set of interface structures including copper and liquid water, and its accuracy is determined by comparing the predicted energy (or forces) with DFT. The size effect on thermal conductivity has been considered and validated using DLP. The DPMD simulations exhibit a reasonable prediction of the thermal conductivity, radial distribution functions (RDFs), vibrational densities of states (VDOS) and density distribution curves of water in the nano-channel. Moreover, the predicted interfacial thermal conductance across the copper-water interface is  $2.505 \times 10^8 \text{ W m}^{-2} \text{ K}^{-1}$ , the same order of magnitude as LJ potentials and experimental results.

## 2. Computational methodology

### 2.1. Data acquisition and training

The rationality, consistency, and completeness of the training structures are crucial to yield reliable and accurate DLPs. Prior to training DLPs, we first constructed a copper (010)-water interface structure consisting of 139 atoms (64 copper atoms and 25 water molecules), following previous literature reports.<sup>22,32</sup> The deep potential generator (DP-GEN)<sup>33</sup> active-learning package was employed to generate training datasets. Three main steps were followed including exploration, labeling, and training, and more details are given in ref. 33 and 34.

To initialize the workflow, we performed AIMD simulations to generate initial training datasets and trained four DLPs with different random seeds. Further details can be found in Section III of the ESI.†

**Exploration.** This step aims to explore the configuration space based on MD simulations with the initial DLPs. DPMD simulations

were performed by running canonical ensemble (NVT) at various temperatures (280 K, 290 K, 300 K, 310 K, and 320 K). In addition, to generate more abundant configurations, we selected a couple of different structures from AIMD trajectories as the initial structures.

To sample reasonable configurations from DPMD trajectories, we introduced the model deviation  $\varepsilon$ , which is defined as the maximum standard deviation of the predictions for the atomic forces:

$$\varepsilon = \max_i \sqrt{\langle \|F_i - \langle F_i \rangle\|^2 \rangle} \quad (1)$$

where  $i$  is the atomic index,  $F_i$  is the atomic force and  $\langle F_i \rangle$  represents the average of four different DLPs. Similarly, an upper and lower bound of the trust levels,  $\varepsilon_{\text{hi}}$  and  $\varepsilon_{\text{lo}}$  are used; only configurations whose model deviations  $\varepsilon$  fall between the bounds will be considered for DFT calculations in the labeling stage. Here we set  $\varepsilon_{\text{lo}} = 0.12 \text{ eV \AA}^{-1}$  and  $\varepsilon_{\text{hi}} = 0.25 \text{ eV \AA}^{-1}$ .

**Labeling.** In this stage, the configurations within the model deviations will be labeled for DFT calculations. The projected augmented wave (PAW) method<sup>35</sup> and the generalized gradient approximation of Perdew-Burke-Ernzerhof (PBE)<sup>36</sup> functional are used in the DFT calculations with the Vienna Ab Initio Simulation Package (VASP)<sup>37</sup> software. The cutoff energy for the plane wave expansion is set to 500 eV, and the Brillouin zone is sampled at the  $\Gamma$  point. The SCF energy convergence threshold is chosen to be  $10^{-6}$  Hartree/atom. Recent studies<sup>27,30</sup> showed that the dispersion-corrected DFT accounts for a large proportion of computational accuracy, especially for water and metal-water systems. Hence, the PBE functional with a D3 dispersion correction<sup>38,39</sup> was used.

**Training.** The reference configurations in the Labeling step were added to the training data. A total of 9505 *ab initio* snapshots are generated for the DLP training.

We adopted the DeepMD-kit<sup>40</sup> software to train data and fit potentials, implemented by the deep learning framework TensorFlow.<sup>41</sup> The system energy is decomposed into the energy per atom

$$E = \sum_{i=1}^{N_{\text{atom}}} E_i \quad (2)$$

where  $E_i$  (atomic energy) is determined by the local chemical environments of the atom within the radius cutoff  $R_c$ .

$$E_i = E_{s(i)}(R_i, \{R_j | j \in N_{R_c}(i)\}) \quad (3)$$

where  $N_{R_c}(i)$  denotes the index set of the neighbors of atom  $i$  within the radius cutoff  $R_c$ , and  $R_i$  represents the atomic coordinate. To guarantee the translational, rotational, and permutational symmetries of the PES, the DeepMD-kit employs the descriptors ( $D_{ij}^\alpha$ ) to map atomic positions into chemical descriptor information.

$$\{D_{ij}^\alpha\} = \begin{cases} \left\{ \frac{1}{R_{ij}}, \frac{x_{ij}}{R_{ij}}, \frac{y_{ij}}{R_{ij}}, \frac{z_{ij}}{R_{ij}} \right\}, R_{ij} \leq R_{\text{cs}} \\ \left\{ \frac{1}{R_{ij}} \right\}, R_{\text{cs}} < R_{ij} \leq R_c \end{cases} \quad (4)$$

The superscript  $\alpha$  can have values of 0, 1, 2, and 3. When  $\alpha = 0$ , only radial information, is used, while using  $\alpha = 0, \dots, 3$

indicates full radial and angular information are used for model training. Further details are available in ref. 42 and 43 DeepMD-kit has implemented the descriptors of 'se\_e2\_a', 'se\_e2\_r', and 'se\_e3'. For 'se\_e2\_a', the notation means that the descriptor is constructed from all information (both angular and radial) of atomic configurations. The e2 stands for the embedding with two-atoms information. Only the radial information of atomic configurations is included in the descriptor 'se\_e2\_r'. Similarly, both angular and radial information are integrated into the descriptor 'se\_e3'. The embedding takes angles between two neighboring atoms as input (denoted by e3). The detailed information can be found in ref. 40 and 43 The descriptor 'se\_e2\_a' was applied, and the size of the embedding neural network and fitting neural network was set to {25, 50, 100} and {240, 240, 240}, respectively. The smooth cutoff ( $R_{cs}$ ) and radius cutoff ( $R_c$ ) were chosen to be 0.5 Å and 6.0 Å, respectively. Besides, the Adam stochastic gradient descent method<sup>44</sup> was used to optimize the model parameters while minimizing the loss function

$$L(p_e, p_f, p_\zeta) = p_e \Delta \varepsilon^2 + \frac{p_f}{3N} \sum_i |\Delta F_i|^2 + \frac{p_\zeta}{9} \|\Delta \xi\|^2 \quad (5)$$

where  $\Delta$  denotes the differences between the training data and DPMD prediction,  $N$  is the number of atoms,  $\varepsilon$  represents energy per atom,  $F_i$  is the force on atom  $i$ , and  $\zeta$  is the virial tensor, respectively. Note that no virial data were included in the training process, we set  $p_\zeta = 0$ . The starting prefactors were 0.02 and 1000 for the energy and force errors, respectively, which means that the training process was initially dominated by force-fitting. The learning rate decreased exponentially from the initial  $1.0 \times 10^{-3}$  to  $3.5 \times 10^{-8}$  with the decay rate and decay step equaling 0.95 and 5000, respectively.

## 2.2. DPMD simulation

DPMD simulations were completed by the LAMMPS<sup>45</sup> software, which had been interfaced with the DeepMD-kit. To study the thermal transport across the copper–water interface, a nano-channel was constructed, as shown in Fig. 1. Two plates consisting of copper atoms were located at the bottom and top, respectively. The bottom plate consists of five layers of copper atoms arranged horizontally, and the outmost layer was fixed to prevent other atoms from moving. The middle two layers called "phantom atoms" were considered as heat sources

connected to an external thermostat. The two innermost layers were in direct contact with water molecules. The top copper atoms were configured in the same way.

After constructing the nano-channel, the geometry optimization was performed using the conjugate gradient (CG) algorithm. Then, the system was relaxed for 0.2 ns with a timestep of 0.5 fs under the NPT ensemble, and the relaxation temperature was set at 300 K *via* a Nosé–Hoover thermal bath. The system's energy, temperature, and pressure changes were monitored until reaching equilibrium. A dynamical simulation run in the microcanonical ensemble (NVE) was performed. To explore heat transport, a temperature difference of 40 K was applied between the bottom (hot) and top (cold) plates. The bottom plate was heated up to 320 K, and the temperature of the top plate remained at 280 K by the Langevin method.<sup>46</sup> In particular, since the cutoff radius of each atom has been specified during the training process, there is no need to reset the cutoff radius here. Periodic boundary conditions were set in all directions and the visualization was realized using the OVITO<sup>47</sup> software. To assess the accuracy of DLPs relative to empirical potentials, the thermal transport properties were also simulated with Lennard Jones (LJ) potentials. Two common water models, TIP4P<sup>48</sup> and SPC,<sup>49</sup> were used to perform CMD simulations.

## 3. Results and discussion

### 3.1. Validation of DLP model

To validate the trained DLP, we randomly chose 50 Cu–water interface data (not included in the training data) as testing sets to estimate the energy, forces, and root mean square error (RMSE). In Fig. 2, the predicted energy and force by DLP are excellently consistent with DFT. The RMSEs for the interface are quite low (1.7804 meV per atom for energy and 73.973 meV Å<sup>-1</sup> for force) and the coefficient of determination is close to 1. The excellent agreement between DLP and DFT has confirmed its high accuracy and capability for further thermal transport property predictions.

The RDFs can reflect the structural properties of confined water in the nanochannel. To further evaluate the accuracy of DLP in describing the structural evolution process, we built a copper–water interface of 139 atoms and performed both

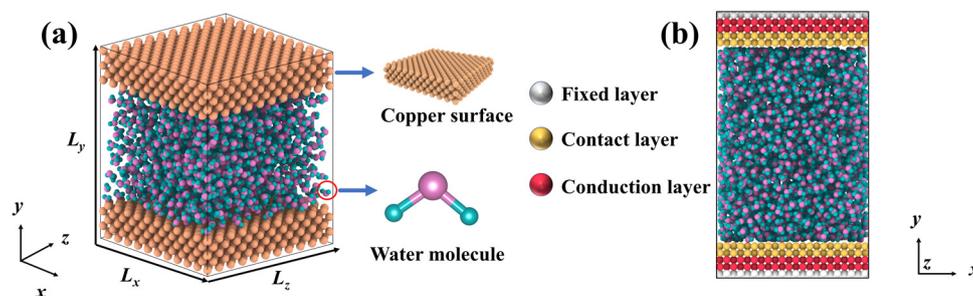

Fig. 1 (a) Schematic diagram for liquid water embedded in the nano-channel composed of copper atoms, and (b) the simulation setup of the NEMD method and the thermostat is applied to the bottom and top plate, respectively.

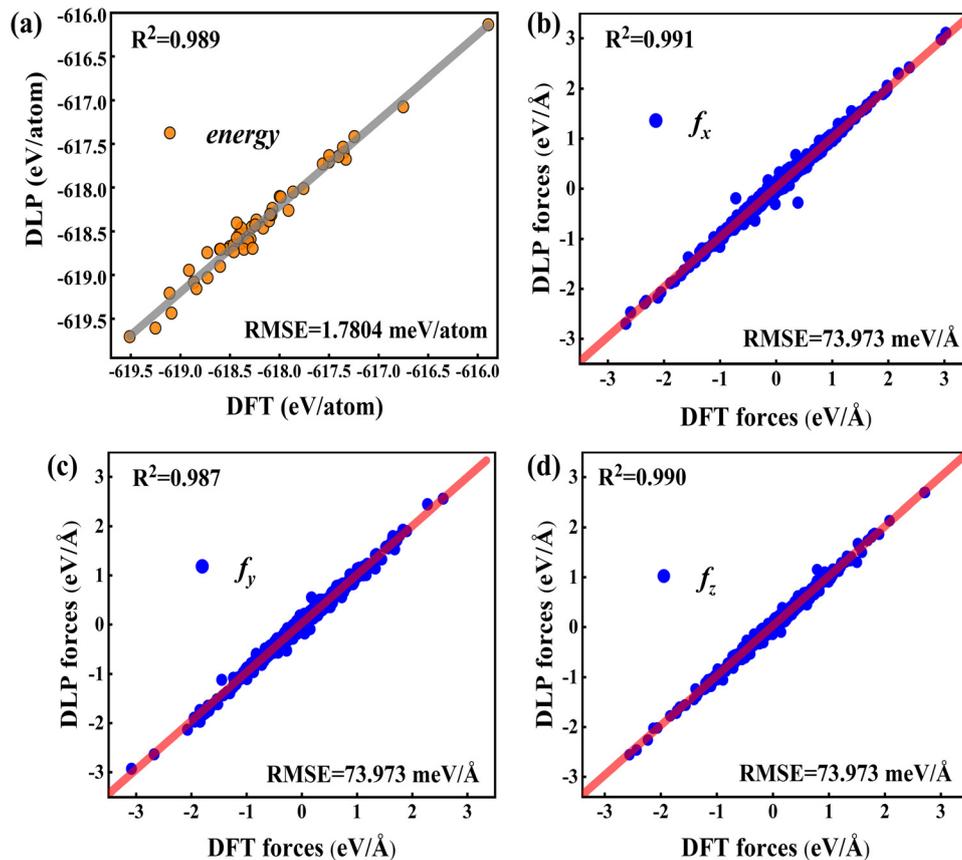

Fig. 2 (a) Comparison between the DFT energies per atom and the DLP prediction, and (b–d) comparison between the DFT forces and DLP prediction in different directions. The red line denotes the fitting curve, and the blue dots and black dots represent the force coordinates and energy coordinates, respectively.

DPMD and AIMD simulations at 300 K. Considering the computational cost, AIMD and DPMD run 9200 steps with a time-step of 0.5 fs. Due to the copper atoms being motionless during the heat transfer, we only considered the RDFs of water, and the average RDFs of the last 2000 configures are calculated and compared, as shown in Fig. 3. For oxygen–hydrogen RDFs, DPMD is highly consistent with AIMD in terms of peak intensity and trend. It should be noted that in Fig. 3(b) and (c), at  $r > 3.5$  Å, the RDFs obtained from DPMD are slightly higher than AIMD results due to the limited statistics and small system size of AIMD. Aside from this region, DPMD simulations reproduce well the RDFs trend from AIMD calculations. Additional validation tests are reported in the ESI,<sup>†</sup> where we compare the RDFs of water resulting from the large system and small system. It can be concluded that DLP not only describes the dynamic characteristics of the system with the accuracy of DFT, but also generalizes the accuracy of DFT to the larger system. Moreover, we also compare the VDOS of water and copper as obtained from 4.6 ps of AIMD, CMD and DPMD simulations of the copper–water interface. The VDOS is calculated from the Fourier transform of the velocity autocorrelation as follows:

$$G(\omega) = \frac{1}{\sqrt{2\pi}} \int_{-\infty}^{+\infty} \langle v(0) \cdot v(t) \rangle e^{-i\omega t} dt \quad (6)$$

where  $v$  represents the atomic velocity,  $\omega$  is the phonon frequency and the angle brackets indicate the ensemble averaging. As shown in Fig. 3(d), the VDOS of copper is maintained to the low-frequency region ( $< 14$  THz) and those three curves show the same change trend except for the differences in peak position and intensity. The VDOS values of water are broadly distributed in the range 0–50 THz. Surprisingly, the peak position at high frequency (50 GHz) predicted by DPMD is almost identical to the AIMD result, which is not found in the CMD result. Further analysis reveals that the high frequency peak is caused by the vibration of the hydrogen atoms, whose potential energy contribution is neglected during the CMD simulations. It is noted that DPMD cannot repeat the VDOS curve as precisely as it can reproduce RDF due to the complexity of the solid–liquid interface structure and potential energy surface, which is beyond the scope of this work.

### 3.2. Size effect of NEMD simulation

The size effect has been a challenge in NEMD simulations according to previous studies.<sup>50,51</sup> Research indicates that the cross-sectional area has less influence on the thermal transport properties, while the thermal transport properties are more sensitive to the channel height.<sup>52,53</sup> To verify this, size factors affecting thermal conductivity have been analyzed using DLP.

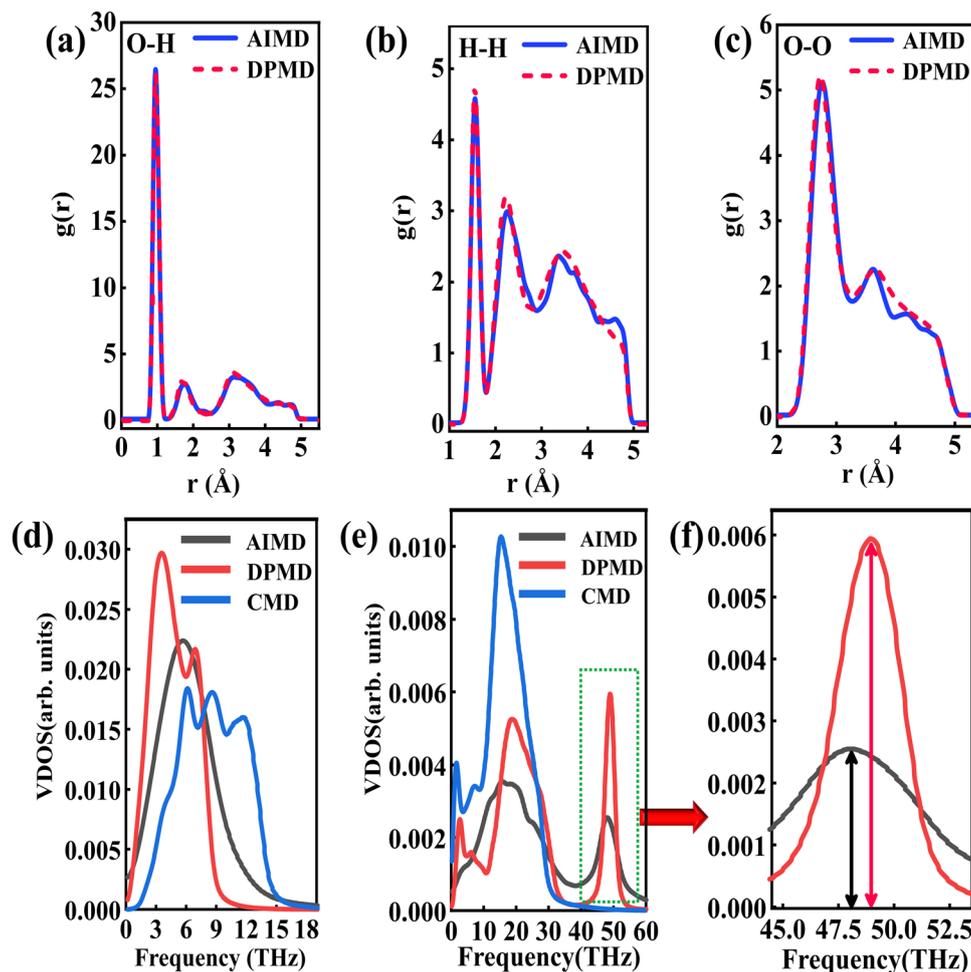

Fig. 3 (a) O–H radial distribution function comparison between the DPMD and the AIMD, (b) H–H radial distribution function comparison and (c) O–O radial distribution function comparison. (d) The vibrational density of states of the Cu surface. (e) The vibrational density of states of the water and (f) partial enlargement (43.5–53 THz) of high frequency peaks.

Five types of nano-channels were prepared with the cross-sectional areas of  $10 \text{ \AA} (x) \times 39 \text{ \AA} (z)$ ,  $15 \text{ \AA} (x) \times 39 \text{ \AA} (z)$ ,  $20 \text{ \AA} (x) \times 39 \text{ \AA} (z)$ ,  $25 \text{ \AA} (x) \times 39 \text{ \AA} (z)$  and  $34 \text{ \AA} (x) \times 39 \text{ \AA} (z)$  and the same channel height ( $46.5 \text{ \AA}$ ). Next, we perform a non-equilibrium molecular dynamics (NEMD) simulation with the DLP to predict thermal conductivity of liquid water embedded in the nano-channel. The nano-channel is relaxed at 300 K, and the initial density of the liquid water is  $1 \text{ g cm}^{-3}$  corresponding to the normal conditions. The water temperature profiles and smoothed results (inserted figure) predicted with different potentials are shown in Fig. 4(a). It is observed that the water temperature for all the potentials consistently increases to the target temperature (300 K) due to the heating from the copper surface. Since the temperature of the heat source and heat sink are set to 320 K and 280 K, respectively, the average temperature of liquid water should be about 300 K after the system reaches thermal equilibrium. Our trained DLP successfully predicts the stabilized temperature of 300 K for the liquid water, the same as empirical potentials (SPC and TIP4P). Fig. 4(b) depicts the cumulative energy input and output through the heat source and heat sink, whose energy difference

maintained at 0 eV suggests that the system has an excellent energy conversion. The energy input and output are fitted by linear curves and the slopes are averaged to obtain the heat flux. To obtain the temperature gradient, the liquid water is equally divided into 27 bins, and the average temperature of each bin is calculated. A clear temperature gradient for water is shown in Fig. 4(c). Once obtaining the heat flux at the solid-liquid interface and the temperature gradient, the thermal conductivity of liquid water can be evaluated following the classical Fourier's law.

In Fig. 5(a), the predicted thermal conductivity remains nearly unchanged as the cross-sectional area increases. We also investigate the influence of channel heights ( $25 \text{ \AA}$ ,  $31 \text{ \AA}$ ,  $39.5 \text{ \AA}$ , and  $46.5 \text{ \AA}$ ), as shown in Fig. 5(b), the thermal conductivity reduces as a function of the channel height. As the channel height increases, thermal conductivity approaches the value of bulk water, which is consistent with empirical potentials.<sup>52,53</sup> Previous studies<sup>53,54</sup> emphasized that the thermal conductivity of water confined in the nano-channel would be relatively larger compared with bulk water due to the interactions between the liquid and solid. Therefore, the length and width of the

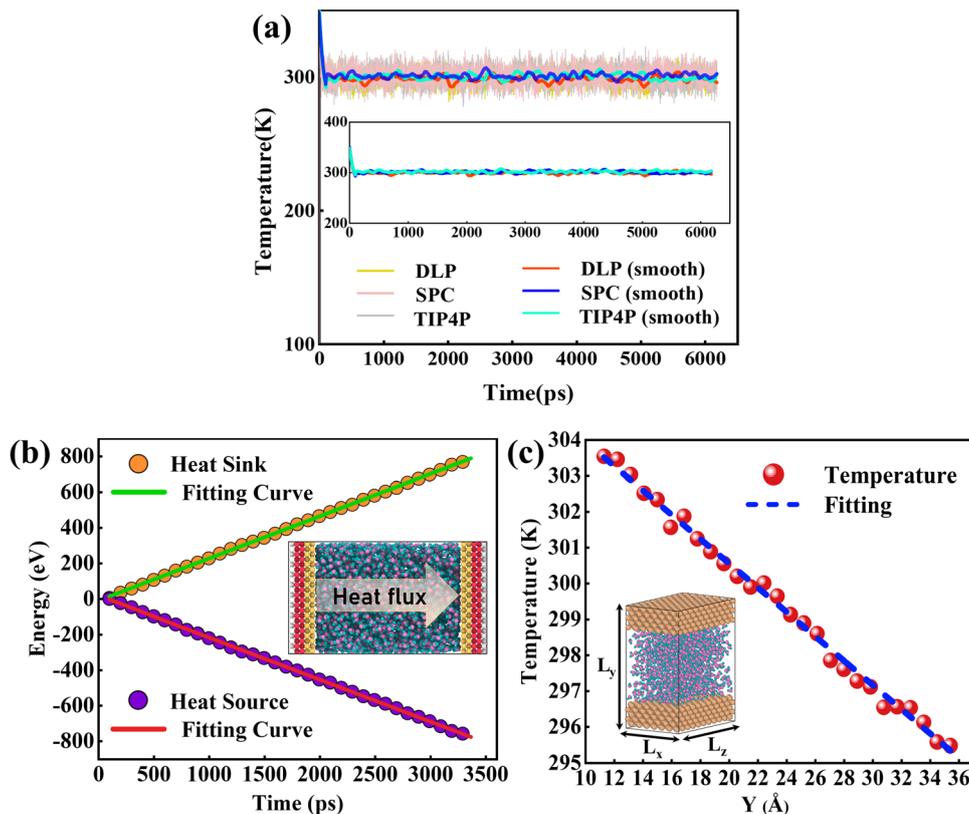

Fig. 4 (a) The temperature variation profiles of liquid water embedded in the nano-channel, (b) the cumulative energy added to the heat source and energy removed from the heat sink and heat flux across the interface is obtained by a linear fitting of the profiles, and (c) the temperature distributions of water in the nano-channel. Note that the heat flux is in units of  $\text{eV ps}^{-1}$  and the temperature gradient is in units of  $\text{K \AA}^{-1}$ .

simulation box should be large enough to eliminate the size effect on the thermal conductivity. A cross-sectional area of  $25 \text{ \AA} \times 39 \text{ \AA}$  and a height of  $46.5 \text{ \AA}$  are chosen in this study to balance computational cost and uncertainty in the results. 918 water molecules are randomly distributed in the middle of the nano-channel with an average density of  $1 \text{ g cm}^{-3}$ .

### 3.3. Density distribution of water

Thermal transport properties across the solid–liquid interface are strongly correlated with the liquid water distribution in the nano-channel. We calculate the density distribution curve of liquid water along the  $y$ -direction. The system box is divided

evenly into 50 bins along the  $y$ -direction, and the number density in the bin is calculated. Water molecules aggregate and appear near the walls, which arises from the interaction between solid and liquid atoms. This interaction promotes the regular arrangement of water molecules near the wall similar to solid atoms, called the “solid-like” layer,<sup>55,56</sup> as shown in the Fig. 6(a). This is more intuitively observed in Fig. 6(b), where the number density changes sharply near the wall, and then oscillates and decays to the average level. In the central region, water molecules distribute uniformly and continuously in a fluid state, corresponding to the relatively gentle position of the number density curve. Compared with LJ potentials, the density

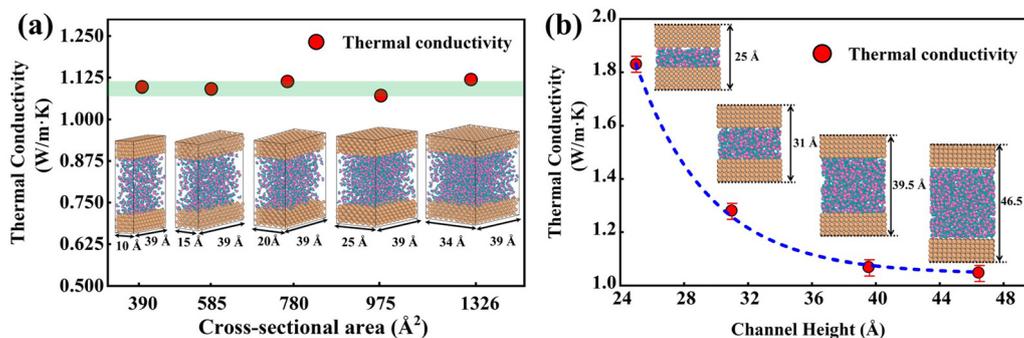

Fig. 5 (a) Thermal conductivity of water with different cross-sectional areas. (b) Thermal conductivity of water with a different channel height.

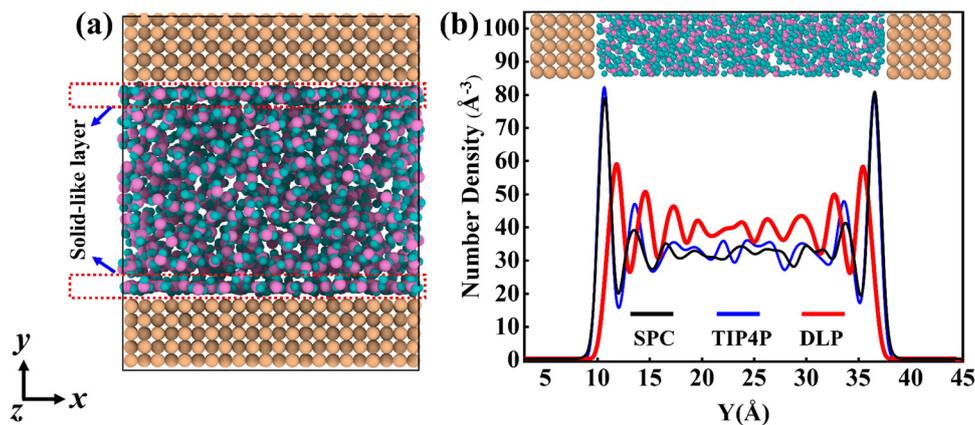

Fig. 6 (a) The thermal equilibrated structures of water layers near the solid wall obtained by dynamical simulations and (b) water density profiles along the  $y$  direction calculated from dynamical simulations with different potentials.

peak appears at 12 Å and 35 Å when using DLP simulations, and the density peak shifts to a certain extent as the intensity decreases. It can be concluded that the adsorption and aggregation of water molecules will also occur on the copper surface,

showing hydrophilicity, but the aggregation state of water molecules is slightly different from LJ potentials. In order to characterize the aggregation state of water molecules, the density distribution profiles of liquid water molecules and

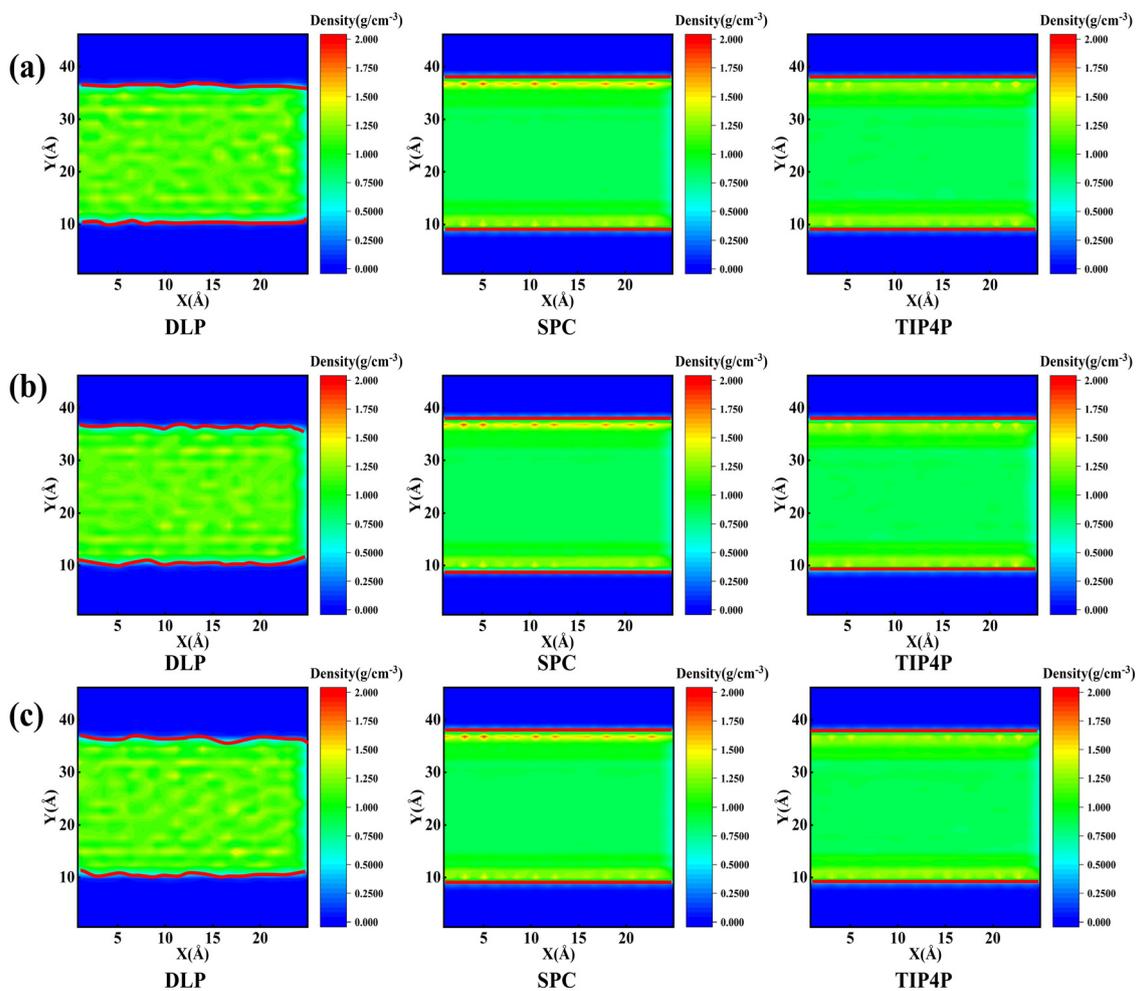

Fig. 7 Mass density distribution profile and morphology of the solid-liquid interface (which is highlighted in the red solid line) for DLP and empirical potentials at (a) 7 ns, (b) 8 ns and (c) 9 ns.

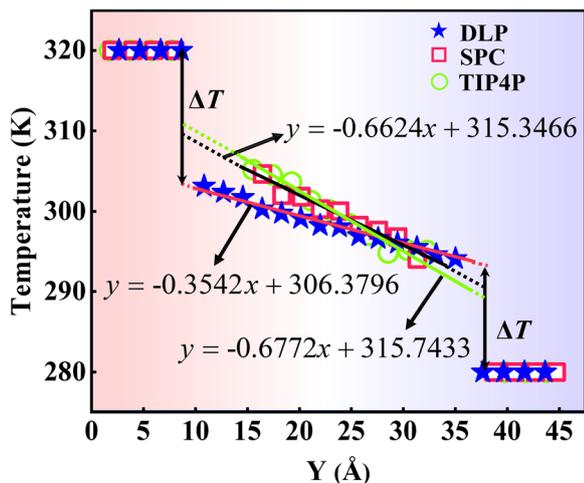

Fig. 8 The temperature distributions along the  $y$  direction calculated from dynamical simulations with DLP and empirical potentials. The  $x$  in the function expression represents the position in the  $y$ -direction, and  $y$  on behalf of temperature.

the corresponding morphology of the solid–liquid interface at 7, 8 and 9 ns are studied, as Fig. 7 shows. Overall, the density distribution of different potentials remains almost constant after reaching the equilibrium state. DLP presents a weak density peak compared to the empirical potential, which corresponds to the results in Fig. 6. In addition, for the solid–liquid interface morphology, DLP exhibits a nonlinearly varying morphology compared to the flatter morphology of empirical potentials. The reason may lie in the form of the potential model and its scope of application. LJ potential describes the two-body interactions at most, and its functional form has been defined. In contrast, the deep neural network (DNN) can be used to approximate any high-dimensional function and has the advantage of characterizing many-body potentials. The DLP based on DNN training is different from the fixed functional form of empirical potentials, and is more like some mapping relationship. From another perspective, a well-designed DNN presents the essential physical image and structural information better than the fixed functional form.

### 3.4. Thermal transport properties of solid–liquid interfaces

ITC is a significant parameter to evaluate thermal transport properties at solid–liquid interfaces. To verify the suitability of the DPMD simulation, we also perform NEMD simulations using DLP and empirical potentials, respectively, to calculate the ITC across the interface. Based on the temperature distribution and heat flux, the ITC across the solid–liquid interface

can be evaluated as follows:

$$G = -\frac{J}{\Delta T \cdot A} \quad (7)$$

where  $J$  represents the heat flux,  $A$  is the cross-sectional area where the heat flux flows, and  $\Delta T$  is the temperature drop across the solid–liquid interface. Heat flux has been calculated in the Size Effect of NEMD Simulation. To determine the temperature jumps, the linear least squares method is applied to extrapolate the linear temperature from the liquid region to the solid surfaces and *vice versa*. Fig. 8 shows a noticeable temperature jump across the solid–liquid interface and the fitting results of the linear temperature. The temperature drop near the heat source is about 17.03 K for the DLP calculation, while that of SPC and TIP4P is 9.95 K and 9.50 K, respectively. At the heat sink, the temperature drop decreases to 13.05 K for the DLP calculation, while that of SPC and TIP4P is 9.70 K and 9.50 K, respectively. The averaged heat flux for the DLP is  $0.22528 \text{ eV ps}^{-1}$  (DLP), while that of SPC and TIP4P is  $0.25782 \text{ eV ps}^{-1}$  and  $0.25323 \text{ eV ps}^{-1}$ , respectively. In Table 1, it is observed that ITC predicted by DLP is  $2.505 \times 10^8 \text{ W m}^{-2} \text{ K}^{-1}$  with a relatively small error ( $\pm 0.335 \times 10^8 \text{ W m}^{-2} \text{ K}^{-1}$ ), while empirical potentials predict a much higher ITC. TIP4P predicts the ITC as  $4.38 \times 10^8 \text{ W m}^{-2} \text{ K}^{-1}$ , and that of SPC is  $4.26 \times 10^8 \text{ W m}^{-2} \text{ K}^{-1}$  and  $4.37 \times 10^8 \text{ W m}^{-2} \text{ K}^{-1}$ , respectively. In addition, ITC is not an intrinsic property and we herein investigate the effect of the thermal bath type, temperature and system size on the interfacial thermal conductance. The detailed results are summarized in Section IV of the ESI,<sup>†</sup> where the original results are used as a comparison. It concludes that DLP predicts ITC in the same order of magnitude as LJ potentials and experimental values,<sup>57</sup> and the results of LJ potentials are much larger as a result of strong solid–liquid interaction. Note that the experimental value is the interfacial thermal conductance of other types of metals (Au) with water. We compute the VDOS to further quantify the solid–liquid interaction. Fig. 9 illustrates the VDOS of the water has an overlap with the copper surface, where the LJ potentials display a larger overlapping area compared to DLP, as shown in Fig. 9(b) and (c). Typically, a large overlap between the VDOS suggests strong interfacial coupling strength and, therefore, produces a reduction in the mobility causing the interfacial liquid to resemble the solid vibrational properties.<sup>58</sup> The strong solid–liquid interaction drives water adsorption on the surface to produce a density peak, which normally promotes the formation of a “solid-like” layer. Compared to LJ potentials, DLP displays a smaller density peak, *i.e.*, a weak “solid-like” layer, resulting in relatively low ITCs.

### 3.5. Evaluation of computational efficiency

Finally, we present a brief summary of the computational efficiency of DPMD simulation. According to the calculation parameters mentioned in the Computational Methodology, it should take the CPU time of  $\sim 217$  h to finish a 4.6 ps AIMD calculation (139 atoms) using one compute node (64 Intel Xeon-Platinum 8375c CPU cores). By comparison, it only takes 125 h to realize a 6200 ps DPMD simulation of 4294 atoms running with a NVIDIA RTX 3090 GPU. A little bit inappropriate is that computational consumption of DLP training is not considered, and different computing platforms are adopted for DPMD and AIMD respectively. More notably, large-scale molecular dynamics simulations with DFT accuracy are expected to be realized, and the computational efficiency could be maintained to a certain extent.

## 4. Conclusions

This work presents a DLP trained on DFT calculations combined with an active learning scheme to investigate the thermal transport process across solid–liquid interfaces. The diversity and integrity of the solid–liquid interface are extended by active learning methods to train a more accurate DLP. Due to the well-described interaction between water and copper, DPMD exhibits excellent performance in predicting the thermal conductivity, RDFs, VDOS and density distribution curves of water at solid–liquid interfaces. Moreover, the average interfacial thermal conductance across the copper–water interface predicted by DLP is estimated to be  $2.505 \times 10^8 \text{ W m}^{-2} \text{ K}^{-1}$ , the same order of magnitude as LJ potentials and experimental results. The VDOS further quantifies the solid–liquid interaction, demonstrating that the existence of solid–liquid interactions and strong coupling prompt heat transport at the interface. This work studies interfacial thermal transport under normal temperature conditions using DLP and obtains uniform results with experiments and empirical potentials. It is expected to develop more accurate DLPs to explore thermal

transport in extreme environments, especially under high temperature and pressure conditions.

## Data availability

Training data and input files for DPMD have been made available at <https://doi.org/10.5281/zenodo.7070848>.

## Conflicts of interest

The authors have no conflicts of interest to disclose.

## Acknowledgements

J.-Y. Y. is grateful for the support from Shandong University (Qilu Young Scholar 89963031). L. L. acknowledges the support from the National Natural Science Foundation of China (Grant no. 52076123).
