**A family of thermally activated delayed fluorescence (TADF) materials functionalized with carboxylate esters is presented herein. Owing to their suppressed concentration-quenching effect in neat films, these ester-functionalized TADF emitters could be applied to the fabrication of non-doped organic light-emitting diodes, demonstrating high external electroluminescence quantum efficiencies of 6.3–18.7%.**

Organic thermally activated delayed fluorescence (TADF) materials have attracted significant attention because of their potential to achieve ~100% internal quantum efficiency (IQE) in organic light-emitting diodes (OLEDs). With these materials, both electrogenerated singlet ( $S_1$ ) and triplet ( $T_1$ ) excitons can be utilized for light emission without using precious metals.<sup>1,2</sup> In the electroluminescence (EL) process of TADF-OLEDs, non-radiative dark  $T_1$  excitons can be upconverted to emissive bright  $S_1$  excitons *via* reverse intersystem crossing (RISC) driven by ambient thermal energy. Among the vast variety of organic TADF materials ever reported, those containing carbonitrile (CN) group(s) as electron-accepting moieties occupy a prominent position because of their facile synthetic accessibility; high thermal, chemical, and electrochemical stabilities; and excellent TADF capability.<sup>1c,3,4</sup> As the first representative, in 2012, Adachi and coworkers reported a series of color-tunable TADF materials based on phthalonitrile, isophthalonitrile, and terephthalonitrile tethered by multiple carbazoles.<sup>1c</sup> These CN-based TADF emitters afforded OLEDs with high external EL quantum efficiencies (EQEs) of up to 19.3%, because of the small singlet–triplet energy gap ( $\Delta E_{ST}$ ) of less than 0.1 eV. In 2016, by connecting four or five 3,6-di-*tert*-butylcarbazole (BCz) arms to a benzonitrile core, Duan and coworkers

developed 2,3,5,6-tetrakis(3,6-di-*tert*-butylcarbazol-9-yl)benzonitrile and 2,3,4,5,6-pentakis(3,6-di-*tert*-butylcarbazol-9-yl)benzonitrile (5BCzBN) as another successful CN-based TADF family.<sup>4</sup> The 5BCzBN emitter exhibited a high EQE of 21.2% and an impressive device operational lifetime of over 770 h in TADF-OLEDs. Despite the brilliant success of CN-based TADF materials, thus far, few studies have explored other isosteric electron-withdrawing groups typified by carboxylate ester ( $\text{CO}_2\text{R}$ ), instead of CN.<sup>5</sup> Thus, exploring the applicability of ester functionalization and, thereby, expanding the chemical space for TADF emitters remains a crucial task.

Herein, we report a new family of ester-functionalized TADF emitters 1–4 (Fig. 1) that combine benzoate, isophthalate, and terephthalate esters as electron-acceptor (A) cores with four or five BCz electron-donor (D) units. Compared to the CN-based 5BCzBN,<sup>4</sup> the corresponding ester-functionalized emitter (2) exhibited a significantly larger reorganization energy of emission ( $\lambda_s$ ) and, thereby, a broader photoluminescence (PL) spectrum because of the larger structural relaxation of  $\text{CO}_2\text{CH}_3$  than that of CN. Additionally, 2 exhibited a considerably high RISC rate ( $k_{\text{RISC}}$ ) of over  $10^6 \text{ s}^{-1}$ , originating from an intense spin–orbit coupling (SOC) based on the ester functionalization. Non-doped OLEDs using 1–4 as neat emission layers achieved high maximum EQEs of 18.7%, 18.0%, 12.4%, and 6.3%, respectively, with relatively small efficiency roll-offs.

Compounds 1–4 were synthesized by the sequence of Fischer esterification and nucleophilic aromatic substitution ( $S_{\text{N}}\text{Ar}$ ) reactions, with commercially available fluorinated benzoic acid, isophthalic acid, and terephthalic acid employed as the starting materials. The detailed synthesis procedures and chemical characterization data are described in ESI.† Peripheral *tert*-butyl groups of BCz can serve as an insulating shell for suppressing the intermolecular electronic interactions and exciton deactivation arising from the collisional Dexter energy transfer,<sup>6</sup> thereby boosting the absolute PL quantum yield ( $\Phi_{\text{PL}}$ ) in the condensed solid states, as discussed later.

As revealed by the time-dependent density functional theory (TD-DFT) calculations (ESI†), 1–4 adopt highly distorted D–A conformations between the peripheral BCz and central

Fig. 1 Molecular structures of ester-functionalized TADF emitters **1–4**.

benzoate (or phthalate) moieties in the optimized geometries. The optimized structure of **2** exhibited large D–A dihedral angles of 60–63° in the ground ( $S_0$ ) state. Accordingly, for **1–4**, the highest occupied natural transition orbitals were mainly localized on the multiple BCz units introduced, whereas the lowest unoccupied natural transition orbitals were distributed over the benzoate or phthalate core, including  $\text{CO}_2\text{CH}_3$  substituent(s), as in the case of analogous CN-based TADF emitters.<sup>1c,4</sup> Such distinct spatial separations of the frontier orbitals for **1–4** resulted in  $\Delta E_{\text{ST}}$  values as low as 13–25 meV in the TD-DFT calculations, suggesting the possibility of efficient ISC/RISC, followed by TADF emission.

X-Ray crystallographic analysis revealed that **2** crystallized in the triclinic space group  $P\bar{1}$ . In the crystal, as shown in Fig. 2, **2** was found to exist as an equimolar mixture of the enantiomeric clockwise (*C*) and counterclockwise (*CC*) propellers, similar to the case of the propeller chirality (atropisomerism) of hexaarylbenzenes.<sup>7</sup> To avoid steric congestion within a molecule, all five BCz propeller blades were tilted in one direction at large D–A dihedral angles of 61–69°, consistent with the foregoing calculation results. This propeller-shaped geometry would be favorable for both lowering the  $\Delta E_{\text{ST}}$  and suppressing the concentration quenching.

Fig. 3a depicts the UV-vis absorption and PL spectra of **1–4** in dilute toluene solutions; the relevant photophysical data are compiled in Table 1. In addition to the intense  $\pi$ – $\pi^*$  absorption bands below 390 nm, all these molecules exhibited rather weak, broad absorptions in the range of 390–430 nm, which can be attributed to the intramolecular charge transfer (ICT) originating from their D–A electronic structures. Upon photoexcitation, **1–4** exhibited blue to orange structureless PL with emission peaks ( $\lambda_{\text{PL}}$ ) ranging from 497 to 598 nm (Fig. 3a and b), whose  $\Phi_{\text{PL}}$  values were in the order of **2** (84%) > **1** (50%) > **3** (31%) > **4** (11%) in the deoxygenated toluene solutions. As in the case of the CN-based **5BCzBN**, the ester-functionalized emitters showed a positive solvatochromism in PL<sup>8</sup> because of the ICT nature of the  $S_1$  state ( $\text{ESI}^\ddagger$ ). Furthermore, **1–4** showed rather

features can be ascribed to the large structural relaxation upon the ICT ( $S_0 \rightleftharpoons S_1$ ). As schematically shown in Fig. 3c, the reorganization energies ( $\lambda_S$  and  $\lambda_S^*$ ) associated with the emission and excitation processes primarily dominate the resulting spectral FWHM.<sup>9</sup> Thus, emitters with larger  $\lambda_S$  (and  $\lambda_S^*$ ) should afford a broad ICT emission. Here, we estimated the actual  $\lambda_S$  values by fitting the PL spectra using the Marcus theory expression (Fig. 3d):<sup>9,10</sup>

$$I_{\text{PL}} \propto \frac{E}{\sqrt{4\pi\lambda_S k_B T}} \exp\left[-\frac{(E_{\text{CT}} - \lambda_S - E)^2}{4\lambda_S k_B T}\right] \quad (1)$$

where  $I_{\text{PL}}$  is the PL intensity as a function of the photon energy ( $E$ ),  $E_{\text{CT}}$  is the energy difference between the  $S_0$  and  $S_1$  states (cf. Fig. 3c),  $k_B$  is the Boltzmann constant, and  $T$  is the absolute temperature. The fitted curves reasonably matched the experimental PL spectra (Fig. 3d), and large  $\lambda_S$  values of 0.51–0.99 eV were deduced for **1–4**. The  $\lambda_S$  of **2** (0.79 eV) was almost two times that of the CN-based **5BCzBN** (0.38 eV). As presented in Fig. 4, the TD-DFT calculations predicted a larger  $\lambda_S$  for **2** (0.73 eV) than that for **5BCzBN** (0.44 eV), which is consistent with the spectroscopic results. As evidenced by the significant change in the dihedral angle ( $\theta$ ) from  $19^\circ$  to  $57^\circ$  between  $S_1$  and

$S_0$  (Fig. 4a), the  $\text{CO}_2\text{CH}_3$  group of **2** was found to adopt a more coplanar arrangement regarding the central benzene core in the  $S_1$  state, whereas it adopted a highly twisted arrangement in the  $S_0$  state. In contrast, for **5BCzBN**, negligible structural changes around the benzonitrile core were observed upon the  $S_1 \rightarrow S_0$  transition (Fig. 4b). Therefore, such a large degree of structural deformation in the ester–benzene dihedral angle ( $\theta$ ) between the  $S_1$  and  $S_0$  structures should be the origin of the larger  $\lambda_S$  and broader PL spectrum of **2** in comparison with those of **5BCzBN**.

Fig. 5 shows the photophysical properties of **1–4** in the pure neat films (see also Table 1 for details). While intense and structureless ICT emissions were observed, the  $\lambda_{\text{PL}}$  positions

Fig. 4 Representation of the structural and spectroscopic differences between (a) **2** and (b) **5BCzBN**. Dihedral angle ( $\theta$ ) between the central benzene core and ester (or nitrile) group at the  $S_1$  and  $S_0$  geometries were simulated using TD-DFT at the PBE0/6-31G(d) level.

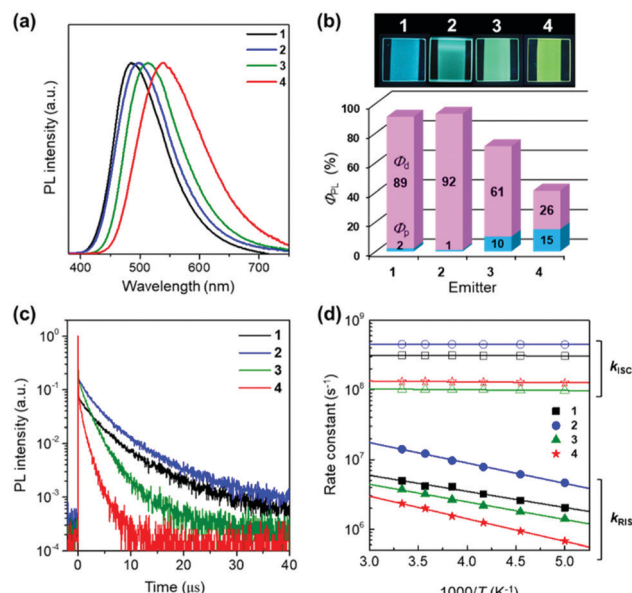

Fig. 5 (a) Steady-state PL spectra, (b) PL images and fractional quantum yields for prompt and delayed fluorescence ( $\Phi_p$  and  $\Phi_d$ ), and (c) transient PL decay profiles of **1–4** in the neat films measured at 300 K under  $\text{N}_2$ . (d) Arrhenius plots of  $k_{\text{ISC}}$  and  $k_{\text{RISC}}$ , measured for the neat films of **1–4**, where the solid lines denote the least-squares fittings.

blue-shifted by 10–60 nm, compare to those in solutions. Notably, the neat films of **1–4** exhibited rather high  $\Phi_{\text{PL}}$  values of 91%, 93%, 71%, and 41%, respectively (Fig. 5b), indicating suppressed concentration quenching even in the condensed solid states. This result is closely related to the capability of aggregation-induced emission (AIE)<sup>11</sup> of these propeller-shaped luminophores (ESI<sup>†</sup>). To further elucidate the TADF behaviors of **1–4**, the transient PL decay characteristics were measured for the neat films (Fig. 5c). Each of the transient PL curves clearly demonstrates two emission components at 300 K and could be fitted by a typical biexponential model. The first component with a lifetime ( $\tau_p$ ) of  $\sim 10$  ns originates from conventional prompt fluorescence (*i.e.*,  $S_1 \rightarrow S_0$ ), and the second, with a lifetime ( $\tau_d$ ) of  $\sim 10$   $\mu$ s, can be assigned to the TADF involving ISC and RISC (*i.e.*,  $S_1 \rightarrow T_1 \rightarrow S_1 \rightarrow S_0$ ). We further assessed the photophysical rate constants of the fluorescence radiative decay ( $k_r$ ), ISC ( $k_{\text{ISC}}$ ), and RISC ( $k_{\text{RISC}}$ ), as listed in Table 1. It is known that lowering the activation energy of RISC ( $E_a^{\text{RISC}}$ ) can accelerate spin-flipping RISC, thereby enhancing the TADF emission.<sup>9,12</sup> Despite that both **2** and **5BCzBN** exhibited comparable  $E_a^{\text{RISC}}$  values of 58 and 56 meV, respectively, the  $k_{\text{RISC}}$  of **2** ( $3.0 \times 10^7 \text{ s}^{-1}$ ) was found to be one order of magnitude higher than that of **5BCzBN** ( $2.8 \times 10^6 \text{ s}^{-1}$ ) at 300 K. Assuming that the excited state population is described by the classical Boltzmann statistical model,  $k_{\text{RISC}}$  is given by the following equation:<sup>9,13</sup>

$$k_{\text{RISC}} = \frac{2\pi}{\hbar} \langle S | \hat{H}_{\text{SOC}} | T \rangle^2 \frac{1}{\sqrt{4\pi\lambda_{\text{RISC}}k_{\text{B}}T}} \exp\left(-\frac{E_a^{\text{RISC}}}{k_{\text{B}}T}\right) \quad (2)$$

where  $\langle S | \hat{H}_{\text{SOC}} | T \rangle$  is the SOC matrix element between the associated T and S states, and  $\lambda_{\text{RISC}}$  is the reorganization energy for the RISC. As shown in Fig. 5d, eqn (2) reproduced the experimental temperature dependence of  $k_{\text{RISC}}$  for **2** with the  $\langle S | \hat{H}_{\text{SOC}} | T \rangle$  value of  $1.29 \text{ cm}^{-1}$ , which was more than three times larger than that of **5BCzBN** ( $\langle S | \hat{H}_{\text{SOC}} | T \rangle = 0.38 \text{ cm}^{-1}$ ). Therefore, the relatively fast RISC of **2** is primarily attributed to its larger  $\langle S | \hat{H}_{\text{SOC}} | T \rangle$ , although **2** contains no heavy metals. We anticipate that the present ester functionalization would be a simple and effective approach for enhancing SOC, thereby accelerating the spin-flipping RISC and shortening the emission lifetime.

Finally, to evaluate the EL performance of **1–4**, we fabricated non-doped TADF-OLEDs with the structure of indium-tin-oxide (ITO, 100 nm)/HAT-CN (10 nm)/TAPC (40 nm)/CCP (10 nm)/**1–4** (20 nm)/PPF (10 nm)/B3PyPB (50 nm)/Liq (1 nm)/Al (100 nm). In

Fig. 6 (a) EL spectra, (b) current density–voltage–luminance ( $J$ – $V$ – $L$ ) characteristics, and (c) EQE vs.  $L$  plots of the non-doped TADF-OLEDs based on **1–4** (Devices A–D).

this device architecture, HAT-CN (2,3,6,7,10,11-hexacyano-1,4,5,8,9,12-hexaazatriphenylene) and TAPC (1,1-bis[4- $N,N$ -di(*p*-tolyl)amino]phenyl]cyclohexane) served as the hole-injection layer and hole-transport layer (HTL), respectively, while B3PyPB (1,3-bis[3,5-di(pyridin-3-yl)phenyl]benzene) and Liq (8-hydroxyquinolinato lithium) were adopted as the electron-transport layer (ETL) and electron-injection material, respectively. In addition, the thin layers of CCP (9-phenyl-3,9'-bicarbazole) and 2,8-bis(diphenylphosphinyl)dibenzo[*b,d*]furan (PPF) with high  $T_1$  energies were inserted at the HTL/EML and EML/ETL interfaces to confine the excitons within the neat EML. Fig. 6a–c shows the EL spectra, current density–voltage–luminance ( $J$ – $V$ – $L$ ) characteristics, and EQE *versus*  $L$  plots of devices A–D using **1–4**, and the key EL parameters are summarized in Table 2. Devices A–D were turned on at 3.6–4.0 V, and they emitted sky-blue to yellow EL with emission peaks ( $\lambda_{\text{EL}}$ ) in the range of 494–544 nm. Among the four devices, devices A and B using **1** and **2** exhibited superior EL performance with a maximum EQE ( $\text{EQE}_{\text{max}}$ ) values of 18.7% and 18.0%, respectively. Consequently, the  $\text{EQE}_{\text{max}}$  values were in the order of

device A (18.7%)  $\approx$  B (18.0%) > C (12.4%) > D (6.3%) (Fig. 6c). The reason for the relatively low EQE<sub>max</sub> values of devices C and D is the substantially lower  $\Phi_{\text{PL}}$  values of 3 and 4 in the neat films.

In summary, a new family of TADF emitters featuring carboxylate esters was designed and synthesized. Their TADF properties were investigated through steady-state and time-resolved photophysical measurements, together with quantum chemical calculations. Compared to the well-studied CN-based analogs, the ester-functionalized TADF emitters tended to exhibit larger  $\lambda_{\text{S}}$  and  $k_{\text{RISC}}$  values. The increase in  $\lambda_{\text{S}}$  can be ascribed to the structural relaxation of the ester groups upon electronic transitions, resulting in broadband emission spectra. These ester-functionalized TADF materials exhibited rather high  $\Phi_{\text{PL}}$  values even in their neat films, owing to the suppression of aggregation-caused quenching. Consequently, non-doped OLEDs based on the neat emission layers achieved high EQE<sub>max</sub> values of up to 18.7%.
