The semimetallic 1T' and 1T phases of two-dimensional (2D) transition metal dichalcogenides (TMDs) have been attracting considerable attention as promising materials for electrochemical technologies owing to their intrinsic electrical conductivity and exceptionally high ion-intercalation properties. Achieving the 1T' phase of MoS₂ in high concentration and preserving it during device operation are still pressing challenges as the phase is metastable. Herein, we demonstrate 3D printed electrodes of 1T'/1T MoS₂/TiS₂ nanosheets for microsupercapacitors. The highly concentrated water-based inks of exfoliated 1T'/1T MoS₂/TiS₂ nanosheets were suitable for the printing of 3D architectures with arbitrary geometry, micron-sized features and spatial uniformity. Such architectures are used as microsupercapacitor electrodes which exhibit an areal capacitance of 448.16 mF cm⁻² at a current density of 0.1 mA cm⁻². TMD-based microsupercapacitors with high-mass loading (up to 100 mg cm⁻²) 3D electrodes also exhibited excellent cycling stability and coulombic efficiency over 100 000 cycles, while retaining the 1T' phase. Overall, the high mass loading of the printed electrode and the conductivity and the geometry of the electrodes contribute to achieving energy and power density (3.89 μW h cm⁻² and 250 μW cm⁻², respectively) which are prime amongst those of the TMD-based supercapacitors. This work demonstrates the possibility of formulating and processing inks of 2D TMDs without conductive additives, paving the way towards the manufacturability of electrically conductive device components based on metastable materials.

Introduction

The crystal phases of TMDs with semimetallic character have been attracting increasing interest in the last decade.¹ Specifically, the semimetallic 1T' phase of MoS₂ has been extensively studied owing to its electrocatalytic properties for hydrogen evolution,² electrical conductivity^{3,4} anisotropic transport and high volumetric capacitance and cyclability.⁵⁻⁷ Thin films of exfoliated MoS₂ nanosheets with a predominant 1T' phase have been reported to exhibit volumetric capacitance in the range of ~400 to ~700 F cm⁻³ in aqueous electrolytes upon intercalation of different ions such as H⁺, Na⁺ and K⁺,^{6,8,9} as well as organic materials without undergoing major structural modifications.

Electron-donating species are likely to be intercalated,¹⁰ while a record areal capacitance of 0.63 F cm⁻² and a corresponding 436 F cm⁻³ volumetric capacitance have been recently reported for compact thin films of exfoliated 1T MoS₂ nanosheets.⁸ Areal capacitance is increasingly reported as a figure of merit for the emerging area of miniaturised energy storage devices for portable electronics including on chip systems for the Internet of Things.¹¹ Indeed, an intercalation reaction occurs where charges are transferred from Li (the intercalant) to the conduction band of the host layered compound. The conversion of the 2H phase into the 1T' phase normally accounts for between ~60–75% of the at% of the material.^{12,13} Additionally, such films have demonstrated an ultrahigh rate of operation, owing to the inherent ability of this class of van der Waals materials to intercalate ions between the layers.^{6,8} Fabricating and testing full devices based on 1T' MoS₂ remains challenging, owing to the metastable nature of this phase. This is not a naturally occurring phase, and it can be obtained *via* lithium treatment of the 2H phase.^{2,14} Additionally, the 1T' phase converts to the 2H phase at temperatures just over 100 °C.^{13,14} Thus, the thermal treatment of an electrode at higher temperatures would make the electrode semiconducting. The process

of lithium intercalation in bulk MoS₂ and exfoliation in water, pursued either electrochemically or chemically, normally produces solutions with concentrations in the order of 0.1 mg mL⁻¹.¹³ TiS₂ is another layered material, and it has been a prototypical cathode material for Li-ion batteries^{15,16} demonstrating capacities and energy densities approaching 250 A h kg⁻¹ and 480 W h kg⁻¹, respectively, and surpassing transition metal oxide cathode materials used for Li-ion batteries. Its fast lithium self-diffusion^{15,17} is amongst the highest reported, thus favouring fast kinetics. It presents a thermodynamically stable 1T phase which exhibits semimetallic properties and it can easily intercalate Li-ions.^{18–21} Thus, blending exfoliated MoS₂ nanosheets in a predominant 1T' phase and 1T TiS₂ nanosheets would ensure the formation of an electrically conductive network with Li-intercalation properties and with van der Waals forces able to create an interconnected network of flakes. These characteristics would make such a blend promising as a supercapacitor electrode.

We have demonstrated the formulation of highly concentrated inks with 50 wt% of 1T'/1T semimetallic MoS₂/TiS₂ in water which are 3D printable *via* robocasting, also known as direct ink writing. They have been deposited in a layer-by-layer fashion *via* robocasting to fabricate symmetric micro-supercapacitor electrodes with micron-sized features which can be tested as they are, without the need for thermal treatments. The micro-supercapacitor demonstrated a prime areal capacitance of 448.16 mF cm⁻² with an energy and power density of

3.89 μW h cm⁻² and 250 μW cm⁻², respectively. The electrodes exhibit excellent cycling stability and coulombic efficiency over 100 000 cycles, while retaining most of the 1T'/1T phase after the electrochemical tests. The additive manufacturability of water based TMD inks paves the way for the development of 3D energy storage devices for use in wearable electronics.

Results and discussion

In this work, we have blended exfoliated 1T' MoS₂ and 1T TiS₂ nanosheets to 3D print micro-supercapacitors. We have chosen 3D printing in the form of direct ink writing as a manufacturing technique as it offers the possibility to design electrodes with arbitrary geometry and dimensions. Additionally, it is viewed as a sustainable manufacturing technique which could also lead to produce devices at scale. Considering the pseudocapacitive nature of 1T' MoS₂ (ref. 6 and 8) and the high intrinsic conductivity of 1T TiS₂,²² we have anticipated that the pseudocapacitive charge storage and the electrochemical adsorption-desorption response at the interface between the electrode and electrolyte will be enabled, which can lead to efficient charge transportation toward high-performance micro-supercapacitors. We do not anticipate a clear coulombic contribution from TiS₂ due to the nanosized dimension of the platelets.²³ The uniqueness of our scalable exfoliation of MoS₂/TiS₂ nanosheets relies on the non-hazardous and water-based amphiphilic properties of a thermoresponsive co-block polymer

(poloxamer). The latter enables the dispersion of the platelets and the achievement of high concentration ($>1 \text{ mg mL}^{-1}$) *via* steric and electrostatic stabilization.²⁴ The resulting formulation is printable *via* continuous extrusion over three dimensions using a robocasting technique. The poloxamer of choice is Pluronic F127 which consists of a poly(propylene oxide) block between two poly(ethylene oxide) blocks. This is a non-hazardous, biocompatible, and commercially available polymer. The first step of the ink formulation is the lithiation of the bulk powders of MoS_2 and TiS_2 using LiBH_4 at $350 \text{ }^\circ\text{C}$ for 3 days²⁵ (Scheme 1a, detailed Li-intercalation and exfoliation mechanisms have been included in ESI Page 1[†]). Upon lithium-ion intercalation, the layered 2H MoS_2 bulk powders undergo a partial phase conversion to the 1T' phase (Scheme 1b). This lithiation process leads to the conversion of more than 50% of 2H MoS_2 into 1T' MoS_2 , as elucidated by XPS analysis (ESI, Fig. S2[†]), while upon Li intercalation the TiS_2 platelets preserve the 1T phase and show negligible oxidation (Fig. S2g[†]). The

subsequent step is exfoliation into atomically thin nanosheets, which occurs by dispersing the lithiated powders with a water-based poloxamer solution (Scheme 1c). A vigorous reaction of lithium ions with water occurs, liberating H_2 which is responsible for the separation of the platelets and the formation of single- and few-layered TMD nanosheets with a lateral size in the micrometre range (Scheme 1d). The highest printable concentration achieved is 50 wt% of $\text{MoS}_2/\text{TiS}_2$. The ink was homogenized without adding any further stabilising agent (Scheme 1e). The thermoresponsiveness of Pluronic enables controlled gelation, which is necessary during the printing process to retain the imparted shape (Scheme 1f). The printability of the inks was investigated *via* rheological characterisation. As shown in Fig. 1a oscillatory measurements show the ink behaving like a solid material at rest with a storage modulus of 10^5 Pa . The ink is also able to flow when a stress is applied. Materials concentrations lower than 50 wt%, such as 30 wt%, exhibit a lower storage modulus (ESI, Fig. S1[†]). The very high

mass concentration of our inks provides a viscosity of $\sim 10^2\text{--}10^3$ Pa s (at a shear rate of 10 s^{-1}), which is much higher than the viscosity normally achieved for inkjet printing, and it is amongst the highest for 3D printing (Fig. 1b). Fig. 1c shows a flow ramp which is indicative of a shear-thinning behaviour. When the shear rate increases, the viscosity drops by orders of magnitude to facilitate extrusion from the syringe. The good rheological properties displayed by the inks allowed the printing of structures with different geometries. Multi-layered, interdigitated, serpentine, and square structures (Fig. 1d) show the stability of unsupported inks without buckling, while woodpile structures show the ability of printing spanning structures. Curved and circular structures of different heights were also demonstrated (Fig. 1d). Computed tomography characterisation (Fig. 1e and f) shows the regularity of the printed serpentine and woodpile structures across layers and the absence of sagging or buckling inside the structures.

The regularity of the structures has been also observed *via* SEM characterisation (Fig. 2a). Cross sectional SEM imaging (Fig. 2b) of the printed struts shows a dense interconnected network of exfoliated flakes of lateral sizes in the range of hundreds of nanometres forming the electrodes. The images were collected after performing a post-printing annealing step to remove the poloxamer to aid the SEM imaging of the microstructure of the struts (Fig. 2c). Bright field TEM imaging shows atomically thin flakes of exfoliated MoS₂ and TiS₂ with lateral sizes over 1 μm as ink components (Fig. 2d and ESI, Fig. S4 and S5[†]). A thorough examination of the exfoliated flake edges reveals that single-layered flakes can be achieved (Fig. 2e), and few-layered flakes are often found too. The materials can partially restack, despite the stabilisation by Pluronic. This could be evidenced by the frequently observed moiré patterns,^{39,40} originating from the angular rotation of restacked single layers (Fig. 2f). Upon lithiation and exfoliation in Pluronic, TiS₂ retains the 1T crystal phase of the bulk counterpart as confirmed by the relative intensities of the {100} and {110} diffraction spots in the respective selected area electron diffraction (SAED) patterns (ESI, Fig. S4[†]), and the flakes display a regular crystalline structure (ESI, Fig. S4[†]). On the other hand, MoS₂ undergoes a 2H to 1T' crystal phase conversion upon Li intercalation,⁴¹ and the 1T' phase is mostly preserved in the resulting inks (Fig. S2[†]). The superstructures of two overlapped $2a \times a$ lattices rotated by 120 degrees are often seen in the SAED patterns of few-layered MoS₂ flakes (Fig. 2d inset and S5b[†]). These $2a \times a$ lattices arise from the zigzag distortion in the transition metal plane that is characteristic of the distorted 1T MoS₂ crystals (1T').^{42,43} The observed superstructures are likely to originate from the "twins" of two individual 1T single crystals, rather than from the intercalated Li residues (Fig. 2d and S5[†]). It should be noted that although it is likely that trapped Li cations are present in the few-layered exfoliated MoS₂ flakes, the observed superstructures in SAED cannot be caused by cation ordering because of the systematic absence of a set of diffraction spots (ESI, Fig. S5[†]), and thus this proves the presence of the 1T' crystal phase of MoS₂. The conversion of the single layers of MoS₂ back into the 2H crystal phase can be caused by the loss of Li cations in agreement with earlier studies,^{41,44} whereas

trapped in the vdW gaps of few-layered flakes, the alkali metal cations preserve the metastable 1T' phase. The persistency of the 1T' phase of MoS₂ in the printed structures has been attributed to the presence of lithium and lithiated species as detected by secondary ion mass spectrometry (SIMS) characterisation (Fig. 2g–n). The spatial distribution of MoS₂ and TiS₂ flakes throughout a volume of $40 \times 40 \times 40\ \mu\text{m}$ (Fig. 2g–n) of the as-printed serpentine structure was directly investigated by time-of-flight secondary ion mass spectrometry (TOF-SIMS). A homogeneous distribution of both types of nanosheets can be detected. Interestingly, the oxidation of the materials is limited to the topmost layer of the 3D printed structures (Fig. 2i, m and ESI Fig. S6[†]), and MoS₂ and TiS₂ are equally affected. Importantly, time-of-flight secondary ion mass spectrometry (ToF SIMS) characterisation has (Fig. 2g–l) revealed that a fraction of lithiated MoS₂ and TiS₂ is found along with the pristine counterparts. The signal of these lithiated LiMoS₂ and LiTiS₂ species overlaps with that of MoS₂ and TiS₂ suggesting that the presence of intercalated Li species allows the preservation of the 1T' phase of MoS₂, which is key to achieve good electrical conductivity. A confirmation of this hypothesis is the observed decrease in secondary ion yields after annealing (Fig. 2i and m).

Electrochemical performance of 3D MoS₂/TiS₂ symmetric supercapacitors

To evaluate the electrochemical areal performance of the supercapacitor devices based on 3D patterned MoS₂/TiS₂ electrodes, we developed symmetric two-electrode prototype cells with a hydrogel electrolyte at room temperature. The 3D electrodes were tested as printed and were entirely made of MoS₂/TiS₂ (TMDs) suspended in a poloxamer hydrogel, which enables low internal resistance and high electroactive area as discussed below. The hydrogel electrolyte is based on 27% w/v poloxamer and 1 M H₂SO₄. The thermoresponsive behaviour of the poloxamer is exploited to combine liquid-like electrode wetting and gel-like device stability. 1 M H₂SO₄/poloxamer electrolyte is conditioned in the liquid phase at 4 °C, poured into a pre-defined shape over the two electrodes and gradually solidifies at room temperature to form a quasi-solid-state supercapacitor device. The ability of the exfoliated MoS₂/TiS₂ sheets to accommodate a variety of solvated ion intercalants was also examined in a three-electrode system in 1 M aqueous Li₂SO₄ and ZnSO₄ electrolytes (ESI, Fig. S7[†]). These exhibited capacitive cyclic voltammograms at the scan rates investigated (10 000 to 100 mV s⁻¹), suggesting fast and reversible ion adsorption behaviour. MoS₂ and TiS₂ individual structures were investigated in the 1 M H₂SO₄/poloxamer electrolyte (Fig. S8[†]) to assess their individual electrochemical properties. The MoS₂ structures exhibit electrocatalytic side-reactions while the TiS₂ structures are affected by slow ion intercalation. When MoS₂ and TiS₂ nanosheets are combined, the electrochemical stability improves without exhibiting electrocatalytic side-reactions. The electrochemical behaviour of MoS₂/TiS₂ electrodes in terms of rate capability, surface charge resistance and cycling stability, was evaluated using cyclic voltammetry (CV),

Fig. 3 Electrochemical characterisation of printed and thin-film $\text{MoS}_2/\text{TiS}_2$ microsupercapacitors. (a) Cyclic voltammograms of various device components at a scan rate of 100 mV s^{-1} and (b) schematic representation of the electrochemical cell assembly. (c) Current contribution on a 4-layered serpentine structure obtained at a 100 mV s^{-1} scan rate. electrochemical impedance spectroscopy (EIS), galvanostatic charge–discharge (GCD) and chronoamperometric/controlled potential coulometric (CPC) studies. Different electrode configurations (serpentine and woodpile) were compared with thin films to investigate the possible advantage of using 3D structures.

Fig. 3a shows the comparative CV curves of the fabricated microsupercapacitors using the 3D printed structures and thin-film TMDs measured at a constant scan rate of 100 mV s^{-1} . Among the devices measured, the 3D serpentine architectures enable the largest CV integral area, suggesting low resistance and fast charge transport. On increasing the scan rate from 100 to 1000 mV s^{-1} , the CV curves preserve a quasi-rectangular shape, demonstrating a reversible charge storage process without side reactions (ESI, Fig. S9–S11†). Fig. 3b shows the electrochemical cell assembly with $1 \text{ M H}_2\text{SO}_4/\text{poloxamer}$ hydrogel electrolyte. The electrochemical contribution mechanisms of TMDs were quantified using a power law – and a reformulated power law (Fig. 3c and ESI, Fig. S12–S15†). From such an analysis, the charge storage (Fig. 3c) appears to arise from the combination of electrostatic electrical double-layer capacitance and surface to near-surface pseudocapacitance (slow-kinetics) due to reversible ion adsorption and fast intercalation of solvated ions.⁴⁵ Upon increasing the scan rate to over 1000 mV s^{-1} (ESI, Fig. S9–S11†), the CV curves of TMDs demonstrate highly resistive behaviour, which indicates that the accumulated charges are predominantly electrostatic and ion intercalation is possibly not occurring. Monitoring stored charges is instrumental in performance benchmarking but also in comprehending more of the phenomena and mechanisms

behind electrochemical energy storage. The electrochemical behaviour and TMD device charge storage are extracted from CV analysis. However, this method is subjective to polarization effects due to the cyclic nature.⁴⁸ Therefore, a straightforward route which utilises conventional controlled potentiostatic coulometry (CPC) is proposed to examine the electrochemical performance of supercapacitor devices (Fig. 3d–f). Applying a bias voltage over time is a linear way to measure the current.⁴⁹ The method consists of integrating [ESI, eqn (S1)†] the current at a fixed potential and measuring the flow of charges from one electrode to the other. In this way, it is possible to extract and quantify the charges stored at different potentials across the operating potential spectrum with very high accuracy. Given the nature of the technique, we can monitor the electrochemical contribution mechanisms by gauging the charge slope and the self-discharging time (Fig. 3d and e). Additionally, by normalising the extracted charges from the charging step at 0.5 V, we monitored the capacitance which plateaus at maximum values after 100 s (Fig. 3f). The extracted charges and the normalised capacitance were compared between CV, GCD and CPC techniques (ESI, Fig. S18†). From these observations, it is apparent that CPC could be used as an electroanalytical diagnostic tool to monitor charge storage behaviour and intercalation phenomena among other conventional techniques such as GCD and CV.

The electrochemical capacitance of printed microsupercapacitors was characterized using GCD analysis (Fig. 4a and S16†) by varying the current densities between 1 and 0.1 mA cm^{-2} . The GCD curves across this range showed nearly symmetric triangular plots without an internal voltage drop in

Fig. 4 Potentiometric electrochemical characterisation of printed and thin-film $\text{MoS}_2/\text{TiS}_2$ microsupercapacitors. (a) Galvanostatic charge-discharge profiles at a current density of 0.1 mA cm^{-2} between different electrodes (substrate, thin-film, woodpile, and serpentine architectures). (b) Galvanostatic charge discharge stability test over 100 000 cycles at a current density of 1 mA cm^{-2} on a 4 layered serpentine structure and (c) capacitance values extracted from galvanostatic charge-discharge at different current densities in response to the electrode geometry and added layers. woodpile structures, serpentine structures, and thin films. Compared to the thin-film devices, the stacked layers of woodpile and serpentine 3D architectures lead to faster charge storage kinetics and higher areal capacitance, as presented in the capacitance *versus* current density plots in Fig. 4c. Among the devices measured, the 10 layer serpentine-shaped microsupercapacitor exhibits the highest charge-discharge times, which leads to the highest areal capacitance of $448.16 \text{ mF cm}^{-2}$ at a current density of 0.1 mA cm^{-2} . The displayed rate capability is 30.9% at a high current density of 1 mA cm^{-2} .

The measured capacitance and rate capability of 3D TMDs at increased current densities could be attributed to the large ionic diffusivity as evidenced by the kinetic analyses (Fig. S12–S15[†]) and high polarizability of covalently bonded S in the TMDs.⁴⁶ Noticeably, serpentine devices surpass woodpile devices across all current densities and numbers of layers. The high capacitance could be ascribed to the strut stack which enables larger electrolyte ion diffusion paths compared to the woodpile structures and minimizes the resistance. To further investigate the long-term stability of 3D TMDs, rapid charge-discharge measurements were carried out. After 10^5 cycles at a current density of 1 mA cm^{-2} , the device retained more than 99.1% of its initial capacitance with an excellent coulombic efficiency of 99.8% (Fig. 4b). From electrochemical impedance spectroscopy

(Fig. S17[†]), we conclude that the TMD electrodes are readily ionically accessible throughout the operating potential window, demonstrating low charge transfer resistance.⁴⁷ Further rate analyses were carried out to evaluate the effect of the number of printing layers and 3D architectures on the electrochemical performance. Areal, gravimetric, and volumetric capacitance variation as a function of the cycle number was reported as shown in Fig. 4c, S20 and S21.[†] On varying the current densities (from high- to low-current densities), the capacitance also steadily increases for the woodpile and serpentine devices, which suggests that the entire 3D architecture is actively involved in charge storage within their thickness range. This likely originates from the conductivity of the $1\text{T}'/1\text{T}$ metallic phase TMDs that initiates rapid charge transportation, as well as from deep electrolyte penetration into the 3D porous electrodes towards high energy storage properties. These metallic properties are also retained in considerable amount after cycling (Fig. S2[†]). The electrochemical performance of semi-conducting 2H phase printed electrodes (after thermal annealing) was measured for comparison. The $1\text{T}'/1\text{T}$ metallic phase demonstrated a higher integral current and charge-discharge response compared to the 2H phase electrodes, as presented in Fig. S20.[†] The Ragone plot presented in Fig. 4d compares the energy storage performance of our $1\text{T}'/1\text{T}$ phase 3D electrodes

with that of different TMD-based microsupercapacitors reported in the literature. To the best of our knowledge, there were no 3D printed carbon additive-free TMD electrodes, and thus, all comparisons are made with systems where carbon additives were present or TMD based devices that were not 3D printed. Remarkably, the serpentine $\text{MoS}_2/\text{TiS}_2$ micro-supercapacitor exhibited a higher energy density of $3.89 \mu\text{W h cm}^{-2}$ with a maximum power density of $250 \mu\text{W cm}^{-2}$ in poloxamer gel-electrolyte, which are higher than those of the thin-film ($1.3 \mu\text{W h cm}^{-2}$) and woodpile devices ($2.96 \mu\text{W h cm}^{-2}$). Moreover, the serpentine $1\text{T}'/1\text{T MoS}_2/\text{TiS}_2$ devices energy and power densities surpass those of most of the previously reported printed TMDs with carbon additive devices (Fig. 4d).^{50–59} The volumetric and gravimetric performances of all device components are reported in Fig. S21–S23.† Overall, the electrochemical behaviour of exfoliated $1\text{T}'/1\text{T MoS}_2/\text{TiS}_2$ nanosheets is attributed to the reversible surface double layer, near surface ion adsorption and solvated ion intercalation in between the sheets mechanisms.^{60,61} Additionally, the scalable printing of semimetallic $\text{MoS}_2/\text{TiS}_2$ inks free from conductive carbon additives enables the fabrication of micro-supercapacitors with prime energy density and power density with unprecedented cycling stability, opening new opportunities for the development of entirely TMD-based energy storage devices.

Conclusions

In summary, we have demonstrated a one step process of exfoliation and aqueous ink formulation of $1\text{T}'/1\text{T MoS}_2/\text{TiS}_2$ nanosheets in very high concentration (50 wt%). The TMD ink was employed for additive-manufacturing of 3D architectures without the aid of conductive additives. We reveal that different architectures lead to different performances of charge storage, due to different diffusion paths of the electrolyte. Specifically, the serpentine-shaped 3D printed TMDs exhibited a high capacitance of $448.16 \text{ mF cm}^{-2}$ at 90 mg cm^{-2} , and 6.5 F g^{-1} and 4.5 F cm^{-3} at 35 mg cm^{-2} with an exceptionally high cycling stability of 99.1% over 10^5 charge–discharge cycles. The energy density of $3.89 \mu\text{W h cm}^{-2}$ at a power density of $250 \mu\text{W cm}^{-2}$ surpasses the present literature values for TMD based supercapacitors. This work paves the way towards the scalable production of semimetallic TMD inks without using any conductive additives for 3D printing of microelectrodes, which can be foreseen to have a broad range of applications, such as in energy storage devices, electrochemical sensors, and water-splitting applications.

Experimental section

TMD ink formulation

Molybdenum disulphide and titanium disulphide bulk powders were mixed in a 50:50 molar ratio ($\text{MoS}_2:\text{TiS}_2$) and then combined with lithium borohydride in a glovebox inert environment, with a molar ratio of 1:2.5 (total TMDs: LiBH_4). The mixed powders were gradually heated and held at $350 \text{ }^\circ\text{C}$ for 72 h before cooling down. Heating and cooling were carried out

for a span of 12 h, respectively. Pluronic-F127 powders were dispersed in de-ionized water with a volume of 25% w/v, which was found to be optimal for the carrier hydrogel, and conditioned at $4 \text{ }^\circ\text{C}$. Intercalated powders were transferred in a PTFE fire-proof container, directly exfoliated with one third of the carrier hydrogel volume and quenched with the two others, while stirring continuously to result in 30 wt% and 50 wt% inks of the combined active material *versus* the carrier hydrogel. The subsequent formulation was then homogenised using a commercial planetary mixer conditioned at 2000 rpm for 2 min and defoamed at 2200 rpm for another 2 min, to reorient the exfoliated nanosheets, saturate hydrolysis, remove air bubbles and ensure optimum dispensing flow during additive manufacturing. TMD ink formulations were then stored at $4 \text{ }^\circ\text{C}$. All reagents were purchased from Merck Sigma-Aldrich and were used as received. A commercial conditioning planetary mixer model was purchased from Intertronics, model Thinky ARE-250.

Rheological characterisation

Rheological properties of the TMD inks were investigated using a rotational mapping geometry of 40 mm parallel Peltier Plate steel loaded on a rotational Discovery Hybrid rheometer HR1 provided by TA Instruments, after friction and temperature calibration at a fixed gap of $1000 \mu\text{m}$, $25 \text{ }^\circ\text{C}$ temperature and using a solvent trap to minimise water loss. Oscillatory tests were performed at 10 rad s^{-1} and flow measurements, at a shear rate from 10^{-3} to 10^2 s^{-1} . Each measurement was performed three times with a cleaning and recalibrating stage in between.

Preparation of thin film electrodes

Graphite foil sheets were masked at $1 \times 10 \text{ cm}$ dimensions with 1 layer of 3 M Scotch Magic tape adhesive tape type 810 with $62.5 \mu\text{m}$ thickness. TMD inks were then spread by using a doctor-blade to control the thickness of thin films at $40 \mu\text{m}$ post-drying, and then cut into $1 \times 1 \text{ cm}$ of active material.

3D printing of TMD inks

TMD inks were loaded into 3 mL polypropylene syringes with metal tipped blunt nozzles with inner diameters of 200 and $410 \mu\text{m}$. The syringes were mounted onto the three-axis stage of a custom 3D printer loaded on a gantry crane and subsequently dispensed in different 3D shapes on a variety of flat substrates by using a brushless ball screw and syringe displacement actuators, which provided a feed rate of 6 mm s^{-1} . The 3D shapes were computed aided designs as .stl files and translated into G-code using the manufacturer's proprietary software. Syringes and nozzles were purchased from Nordson EFD precision dispensing systems and the bespoke 3D printer system was from 3D Inks LLC.

Thermal annealing

As-printed architectures were thermally annealed for obtaining the 2H phase in a vacuum tube furnace under an argon flux for 3 h at $470 \text{ }^\circ\text{C}$ with a $25 \text{ }^\circ\text{C min}^{-1}$ heating rate.

Materials characterisation

Scanning electron microscopy. The surface morphology of the as-printed 3D printed structures was investigated with a Zeiss Auriga 45-25 cross beam electron microscope using a Schottky field emission gun with a Gemini electron column. High-resolution images were obtained with a standard in-chamber ET electron detector operating between 5 and 20 kV of accelerating voltage.

Transmission electron microscopy. Samples for TEM were prepared by drop-casting diluted dispersions of MoS₂/TiS₂ inks on carbon-coated copper grids. The grids were dried overnight under ambient conditions. Low-magnification bright-field TEM images and selected area electron diffraction (SAED) patterns were acquired on a JEOL JEM-2100Plus microscope. High-resolution TEM (HRTEM) imaging was performed using a JEOL JEM-2100F microscope with a field-emission gun operated at 200 kV accelerating voltage.

X-ray photoelectron spectroscopy. XPS spectra were recorded on a Thermo Scientific K-Alpha⁺ X-ray photoelectron spectrometer system. Data were collected at 29 eV passing energy for both the core level (S 2p, C 1s and Mo 3d) and valence spectra.

Time-of-flight secondary ion mass spectrometry. The as-printed 3D electrodes were rastered and mapped over a pre-defined area of 50 × 50 μm with a 25 keV Bi⁺ primary ion beam, as well as depth profiled by surface milling utilising a 25 keV Cs⁺ and Ar⁺ beam reaching up to 50 μm. All measurements were carried out using a Combined IONTOF TOF.SIMS5-Qtac100 LEIS instrument.

X-ray computed tomography. The three-dimensional microstructure of the printed structures was investigated using X-ray microcomputed tomography (Zeiss Versa 620) in a large-field-of-view mode for complete map profiling of two 10 × 10 mm electrodes with different architectures (woodpile and serpentine). The porosity of the filament was calculated from the scan in the central region, segmenting the MoS₂/TiS₂ flakes suspended in the polymeric hydrogel with Avizo software. The tomographic data were segmented into two domains (MoS₂/TiS₂ and air, respectively) using Avizo software *via* greyscale thresholding. The surface area and porosity of the printed woodpile structure were computed considering the surface of the MoS₂/TiS₂ domain (Thermo Fisher Scientific, USA).

Electrolyte formulation. The electrolyte was prepared by gradually dispersing sulphuric acid (H₂SO₄) in a 27% w/v Pluronic solution kept at 4 °C to reach a 1 M concentration of H₂SO₄. The final electrolyte solution was conditioned at 4 °C for 7 days each time.

Electrochemical cell assembly. Woodpile and serpentine architectures of 1 cm² footprint area (*x, y*) and 2–10 layers in the *Z* dimension were 3D printed on graphite foil, and air-dried at room temperature overnight. The structures were then prepared in various printed layers as two-electrode symmetric systems by cutting the substrates into 2 × 1 cm², fixed in position with copper clamps in borosilicate glass cells. The inter-electrode distance was fixed at 1 cm in all experiments. The cell was then assembled by directly pouring 30 mL of the electrolyte

formulation at 4 °C into a beaker, only covering the 1 cm² of the active electrode area and sealing the lid with parafilm.

Electrochemical measurements. Our electrochemical script methodology for each set of electrodes consists of a combination of open circuit potential, impedance spectroscopy, cyclic voltammetry, galvanostatic charge–discharge and chronoamperometric/coulometric measurements. The OCP was ±15 mV in all cases, indicative of electrode symmetry. Cyclic voltammetry was performed in the 0–0.5 V potential window with a scan rate from 0.1–10 000 mV s^{−1} and *vice versa*. Five cycles were performed at each scan rate, of which the third was visualised. Impedance spectroscopy was performed in a frequency range ramping from 0.02–100 000 Hz and 100 000–0.02 Hz with a fixed potential across the whole device operating potential spectrum from 0.0 V–0.5 V–0.0 V, with a 0.1 V step size. Galvanostatic charge–discharge measurements were performed at a fixed current in the 0.1–1 mA range over 100 and 1000 cycles for each current density and over 100 000 for 1 mA (each charge/discharge cycle occurred in 40 s which translates into 41 days of continuous cycling). The 50th cycle was visualised each time. Chronoamperometric/controlled potential coulometric studies were performed across the device operating potential window (0.0 V–0.5 V–0.0 V) with a 0.1 V step size. Prior to any measurement, each cell was conditioned at 0.0 V for at least 120 s. Furthermore, impedance spectroscopy was performed after each set of characterisation studies to gauge the ageing profile. All measurements were carried out using a series of Gamry 1010E interface bipotentiostats/galvanostats.

Author contributions

C. M. conceived and designed the work. A. P., S. T., and C. G. performed the TMD exfoliation, the ink formulation, and the 3D printing. A. P., G. N., S. T., and P. S. performed the device fabrication and the electrochemical characterization. M. S. performed TEM characterization. G. C. performed XPS characterization. F. I. performed X-ray computed tomography. C. M. supervised and guided the study. The manuscript was written through contributions of all authors.

Conflicts of interest

There are no conflicts to declare.

Acknowledgements

C. M. would like to acknowledge the award of funding from the European Research Council (ERC) under the European Union's Horizon 2020 research and innovation programme (Grant Agreement No. 819069), the award of a Royal Society University Research Fellowship (UF160539), by the UK Royal Society UK and the award of the EPSRC grants: EP/M022250/1 and EP/K01658X/1. A. P. would like to acknowledge Engineering and Physical Sciences Research Council (EPSRC) DTP 2016-2017 grant, Dr Sarah Fearn for insights into ToF-SIMS instrumentation and analysis, and Dr Francesco Iacoviello and the National Research Facility for lab X-ray CT (NXCT) measurements

through EPSRC grant EP/T02593X/1. G. C. would like to acknowledge the support of the China Scholarship Council (CSC) Grant #201808060492.
