Influence of ventilatory parameters on the concentration of exhaled volatile organic compounds in mechanically ventilated patients†

Andrea Romano, ^a Matyas Fehervari^a and Piers R. Boshier^{*a,b}

Analysis of volatile organic compounds (VOC) within exhaled breath is subject to numerous sources of methodological and physiological variability. Whilst breathing pattern is expected to influence the concentrations of selected exhaled VOCs, it remains challenging to investigate respiratory rate and depth accurately in awake subjects. Online breath sampling was performed in 20 mechanically ventilated patients using proton transfer reaction time-of-flight mass spectrometry (PTR-ToF-MS). The effect of variation in respiratory rate (RR) and tidal volume (TV) on the VOC release profiles was examined. A panel of nineteen VOCs were selected, including isoprene, acetone, propofol, volatile aldehydes, acids and phenols. Variation in RR had the greatest influence on exhaled isoprene levels, with maximum and average concentrations being inversely correlated with RR. Variations in RR had a statistically significant impact on acetone, C3–C7 linear aldehydes and acetic acid. In comparison, phenols (including propofol), C8–C10 aldehydes and C3–C6 carboxylic acids were not influenced by RR. Isoprene was the only compound to be influenced by variation in TV. These findings, obtained under controlled conditions, provide useful guidelines for the optimisation of breath sampling protocols to be applied on awake patients.

Introduction

The analysis of volatile organic compounds (VOCs) within exhaled breath has emerged as a viable approach to the non-invasive detection of human disease. Previous studies have characterised the distinct VOCs signals of numerous conditions, including cancers,¹ diabetes,² gastrointestinal disorders,^{3,4} heart disease,⁵ liver disease,⁶ respiratory disease,⁷ neurodegenerative disorders,⁸ organ transplantation rejection,^{9,10} oral health problems¹¹ and kidney disease.¹²

A wide variety of analytical techniques have been employed for disease detection in breath, including mass spectrometry either after chromatographic separation or as direct injection technique,¹³ ion mobility spectrometry (IMS),¹⁴ optical and laser-based spectroscopy,^{15–17} electronic noses¹⁸ and nano-material-based gas sensors.¹⁹ The analytical technique used and the fraction of breath being sampled will influence the choice of breath sampling method. Breath can be sampled using bags,²⁰ canisters²¹ or by taking advantage of bespoke solutions either developed in-house or commercial ones.^{22–24} When using gas chromatography-mass spectrometry (GC-MS), a step of pre-concentration is normally carried out by means of

thermal desorption (TD), solid-phase microextraction (SPME) or needle trap devices (NTD).^{25–27} With direct injection methods, pre-concentration is instead not required.

A prerequisite of any diagnostic test before reaching wider clinical practice is an appreciation of inherent sources of physiological and methodological variability. Such knowledge is important for determining thresholds of (patho)physiological variance and the extent to which standardisation is required. This was exemplified by the discovery that exhaled nitric oxide is significantly influenced by expiratory flow and respiratory rate leading to the creation of international consensus guidelines for its measurement.²⁸

In the context of exhaled VOCs, previous authors have studied the influence of respiratory variables (flow and respiratory rate),^{29,30} route of exhalation (oral vs. nasal),^{31–33} body posture,³⁴ and oral cleansing.³⁵ These studies identified that for certain VOCs variation in the conditions of breath sampling had a significant effect on their recorded concentration. A significant challenge faced by studies investigating the effect of respiratory parameters on exhaled VOC levels is the ability to accurately control those parameters in conscious subjects. There have been several previous reports detailing the analysis of exhaled VOCs in anaesthetised and mechanically ventilated patients.^{36–39} Such conditions offer a unique opportunity to study the effects of ventilatory parameters on VOC concentrations.

The current study aims to investigate the impact of both the rate and depth of breathing pattern on the levels of disease

specific VOCs in patients who are anaesthetised and mechanically ventilated. The current study utilises Proton Transfer Reaction Time-of-Flight Mass Spectrometry (PTR-ToF-MS). This analytical technique generates data with high informational content with high time resolution, resulting therefore optimally suited to breath-by-breath online monitoring.

Methods

Study population

All enrolled patients were recruited from Imperial College Healthcare NHS Trust from June 2017 to August 2017. This study was conducted in accordance with the recommendations for physicians involved in research on human subjects adopted by the 18th World Medical Assembly, Helsinki 1964 and later revisions. Regional ethical approval for the study was granted by the Camden and Kings Cross Research Ethics Committee (REC ref: 15/LO/1140). All patients provided informed written consent prior to participation. The study population included both cancer and benign cases, with patients undergoing minor and major as well as open and laparoscopic operations. Intra-abdominal pressure during laparoscopic surgery was maintained throughout all cases at 12–15 mm Hg. Open surgery included gastrectomy from an abdominal approach and oesophagectomy from a right thoraco-laparotomy approach with one lung ventilation during the thoracotomy. Laparoscopic operation included staging laparoscopy, fundoplication, hiatus hernia repair, cholecystectomy and Hellers cardio-myotomy. The details of the study were explained to all eligible patients and fully informed and written consent was obtained prior to enrolment.

Ventilator preparation and general anaesthesia

Before breath sampling, all traces of volatile anaesthetic agents were removed from the ventilation circuit utilising the standard clinical procedure for ventilator preparation in cases of malignant hyperthermia. General anaesthesia was induced with alfentanil and propofol after patients were pre-oxygenated until their expired end-tidal oxygen concentration was over 90%. Total intravenous anaesthesia was maintained thereafter for the duration of the surgery.

VOC analysis

Breath VOC analysis was conducted using a commercial PTR-ToF-MS instrument (PTR-TOF 1000, Ionicon Analytik GmbH, Innsbruck, Austria) equipped with a commercial switch reagent ion (SRI) feature. The SRI feature allows to perform NO^+ and O_2^+ -based ionisation in addition to more commonly used H_3O^+ . Optimal conditions for VOC identification and quantification were defined according to a previously described experimental workflow,⁴⁰ dedicated to method optimization under breath-relevant conditions. Briefly, the workflow consisted of: (i) screening of reduced drift field conditions using different reagent ions, (ii) evaluating the impact of a change in humidity on branching ratios

and (iii) gravimetric calibration using permeation or diffusion tubes.

Gravimetric calibration was performed by connecting the PTR-ToF-MS to a permeation unit (Eco Scientific Stroud, Gloucestershire UK). The permeation unit was used to keep different permeation/diffusion tubes at 60 °C, under a constant nitrogen flow and could be connected directly to the PTR-ToF-MS inlet. Since each permeation/diffusion tube had a known, constant diffusion rate (either because the device was supplied in the form of a certified reference standard or because the diffusion rate had been determined experimentally beforehand), the PTR-ToF-MS signal, typically expressed in normalised counts per second (ncps) could be converted into absolute concentrations (parts per billion or ppb).

The sample inlet consisted of a PEEK heated line (temperature 110 °C, length 1.2 m, inner diameter 0.04). Inlet flow rate was set to 40 ml min⁻¹. NO^+ was used as the reagent ion. This allowed to exploit different reaction channels for the different compound classes of interest and notably hydride transfer for aldehydes, charge transfer for phenols and adduct formation for ketones and carboxylic acids. Optimal conditions for the drift tube were: temperature 110 °C, pressure 2.30 mbar and voltage 350 V, resulting in an E/N of 84 Td (1 Townsend = 10⁻¹⁷ V cm²). Mass spectra were acquired in the 15–265 range of mass-to-charge ratio (*m/z*) at a rate of one spectrum per second. Analyte ions used in VOC determination are summarized in Table 1.

VOC analysis focused on nineteen mass peaks, assigned to compounds previously associated with states of health and disease (Table 1). Isoprene and acetone were specifically included owing to their status as abundant endogenous breath VOCs. C3–C10 aldehydes, C4–C6 carboxylic acids, phenol, methyl-phenol and ethyl-phenol were selected in view of their importance as putative breath biomarkers of gastric adenocarcinoma^{41,42} and colorectal adenocarcinoma.⁴³ The panel of volatile fatty acids was further extended to acetic acid and propanoic acid as they are found in elevated concentrations in the headspace of oesophago-gastric adenocarcinoma tissue samples.⁴⁴ Propofol (2,6-bis(1-methylethyl)-phenol) was used as anaesthetic in all procedures, and was therefore included in the analysis.

Intraoperative breath sampling

Analysis of breath VOCs in response to varying respiratory parameters was performed shortly after induction of general anaesthesia prior to commencing the surgical procedure. Patients' breath was continuously sampled into the inlet of the PTR-MS instrument *via* a T-piece placed immediately distal to the endotracheal tube. This set-up was adapted from the method previously developed for intraoperative breath analysis using Selected ion flow tube mass spectrometry (SIFT-MS).³⁶ VOCs were measured under conditions of varying respiratory rate (RR) and tidal volume (TV) according to a defined protocol (Fig. 1). Baseline ventilation settings for all subjects were: FiO_2 100%; RR 12 min⁻¹, and TV 8 mL kg⁻¹ calculated using ideal body weight. Ventilator parameters, including respiratory rate and tidal volume, were easily changed by the attending anaes-

Fig. 1 Schematic representation of the ventilator experimental protocol. Baseline (constant) ventilation settings were: RR 12 min^{-1} and TV 8 mL kg^{-1} calculated using ideal body weight.

thetist using the ventilator control panel. A 7-minute measurement conducted on a single patient under constant baseline conditions was employed to assess repeatability: measured % RSDs ranged between 2.7% and 21.2% according to the compound (Table S1, ESI†).

In the first experiment RR was varied while keeping TV constant. Starting from the baseline ventilator settings, RR was first set to 5 min^{-1} and kept constant for 30 seconds. RR was subsequently increased in stepwise fashion to 10, 15, 20, 25 and 30 min^{-1} maintaining each rate constant for a 30 seconds period. Settings were then returned to baseline for a minimum of 60 seconds.

In the second experiment, TV was varied while maintaining a constant RR. TV was increased stepwise to 6, 8, 10, and

12 mL kg^{-1} with each step having a duration of 30 seconds. On completion of these experiments, ventilator settings were returned to baseline and thereafter optimised by the attending consultant anaesthetist.

Analysis of background VOCs within the ventilator circuit was performed at the start of each sampling day. Measurements were made for at least one minute using standard ventilator settings (O_2 concentration 100%, tidal volume 550 mL min^{-1} , respiratory rate 12 min^{-1}) with a manual breath bag in the place of the patient's lung.

Data analysis

Data were extracted using PTR-MS viewer version 3.2.2.2 (Ionicon Analytik GmbH, Innsbruck, Austria). Additional data

analysis was conducted using in-house generated scripts written using R programming language.⁴⁵ To obtain a numeric description for each profile, four key parameters were defined for each set of conditions: the maximum (expressed as median intensity of the peak summits), the minimum (median intensity of the peak valleys), the amplitude (difference between maximum and minimum) and the area under the curve (AUC), corresponding to the sum of all values for the time window of interest. To reduce the impact of inter-individual differences, each profile was subjected to a normalisation process whereby the entire profile was rescaled to an arbitrary intensity scale ranging from 0 to 1. A graphical representation of a patient's isoprene profiles with the parameters extracted is reported in Fig. 2. The perusal of the time profile reveals that a few seconds of delay can sometimes be seen in the release pattern with respect to the change of ventilator settings; this was probably due to small operator-related delays in changing ventilator settings.

Following a previously published protocol,³⁹ a well-characterised mass peak (m/z 68.06, corresponding to isoprene) was used as 'tracker' to highlight the different phases of breathing has already been advised. Isoprene's mass peak was also used as reference for the extraction of breath profile parameters from all other masses. A dedicated R package (IsopreneR) was developed for the processing of the isoprene profiles and the source code is available at GitHub (aromano910/IsopreneR: Functions and packages for data processing in breath analysis (github.com)). The 'breath.tracer' function, included within the package, allowed to find points corresponding to local maximums and minimums in all time profiles.

One-way ANOVA was conducted using parameter values as dependent variables and either RR or TV as independent vari-

ables. Statistical significance was established for p -value < 0.05, following correction for false discovery.⁴⁶

Results

Intraoperative breath sampling was undertaken in twenty patients. Details of patient characteristics, including disease status and operation type are presented in Table 2.

The signal of all nineteen VOCs and the corresponding mass peaks, were verified to be significantly lower in the back-

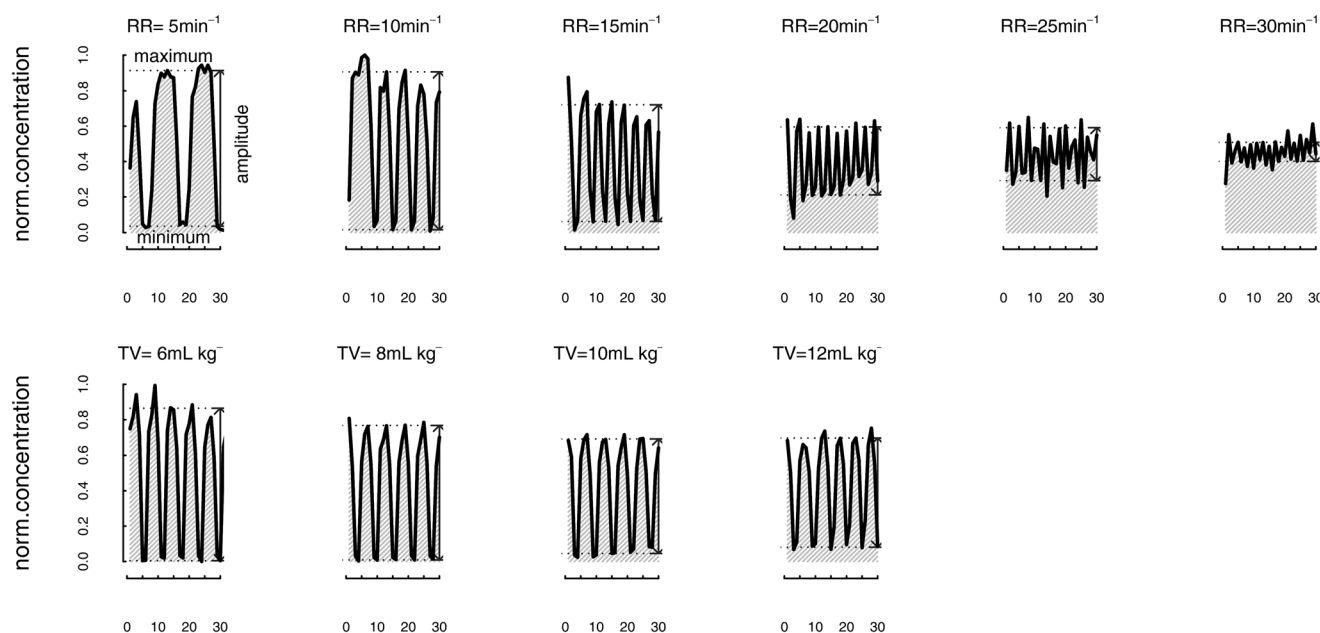

Fig. 2 Breath profiles of isoprene (m/z = 68.06) in patient no.1. Measurements conducted at different values of respiratory rate (RR, top row) and tidal volume (TV, bottom row). Baseline (constant) ventilation settings were: RR 12 min⁻¹ and TV 8 mL kg⁻¹ calculated using ideal body weight.

ground of the ventilator circuit compared to breath (Table S2, ESI†).

Influence of respiratory rate and tidal volume

Of the nineteen VOCs that were studied, isoprene was the most affected with a significant change in all the assessed metrics (signal amplitude, AUC, maximum and minimum signal) in response to varying RR. Furthermore, only isoprene (signal amplitude) was significantly affected by alteration in TV (Fig. 3). Besides isoprene, eight more VOCs showed a significant change in one or more parameters in response to varying RR. Affected VOCs included acetone, C3–C7 aldehydes, acetic acid and propanoic acid (Tables S3 and S4, ESI†). Other compounds of supposedly endogenous origin (C8–10 aldehydes, C4–6 volatile fatty acid and phenols) as well as the anaesthetic agent propofol were not significantly influenced by changing RR and TV.

The data regarding *maximum* values obtained for all the nineteen VOCs are summarised in Table 3. Six VOCs showed significant differences in *maximum*: isoprene, acetone, propanal, pentanal, hexanal and acetic acid. Isoprene (graphically represented in Fig. 3) was the most affected with *maximum* values reaching the highest level for $RR = 5 \text{ min}^{-1}$ and continuously decreasing until $RR = 30 \text{ min}^{-1}$.

The results relative to the remaining five VOCs are graphically represented in Fig. 4. Like isoprene, acetone, hexanal and acetic acid showed a descending trend in *maximum* with the progressive increase in RR. For these three VOCs, *maximum* was significantly higher for $RR = 5\text{--}10 \text{ min}^{-1}$, stable for $RR =$

$15\text{--}25 \text{ min}^{-1}$ and significantly lower for $RR = 30 \text{ min}^{-1}$ (acetic acid only). Short-chain aldehydes propanal and pentanal showed a different behaviour: the highest concentrations were reached at the two extremes of the assessed RR range, whereas the lowest concentrations were observed for $RR = 20 \text{ min}^{-1}$.

Discussion

This work presents original data, showing the impact of a change in ventilatory parameters on the time-resolved profiles of selected VOCs of clinical interest. For the majority of these VOCs this is the first report of their measurement in patients who are intubated and ventilated. The ability to evaluate effects in patients who are mechanically ventilated offers a unique opportunity to achieve fine control over the rate and depth of subjects breathing that historically has not been possible in awake patients. Furthermore, breath sampling *via* an endotracheal tube offers a chance to analyse VOCs that are of systemic (endogenous) origin reducing the potential influence of oral and ambient contaminants.

The principal findings of this study were: (i) for half of assessed endogenous VOCs variation of respiratory parameters did not appear to affect signals levels, (ii) with the exception of isoprene, variation in TV had negligible influence on the levels of selected VOCs and; (iii) a variation in RR affected *maximum* concentrations of six VOCs: of the four extracted parameters, *maximum* appears to be the most significant as it will correspond to the actual VOC concentration in exhaled breath.

Fig. 3 Variation of isoprene breath profile parameters at different values of RR (top row) and TV (bottom row). Statistically significant differences are established by means of one-way ANOVA, followed by Tukey's *post-hoc* (letter notation highlights differences between conditions, $p < 0.05$).

Fig. 4 Effect of respiratory rate (RR) on *maximum* values extracted from breath profiles of selected compounds. Statistically significant differences are established by means of one-way ANOVA, followed by Tukey's *post-hoc* (letter notation highlights differences between conditions, $p < 0.05$).

Exhaled isoprene constitutes one of the most studied VOCs in breath research. Isoprene is thought to be linked to cholesterol biosynthesis through the mevalonate pathway and should therefore be ubiquitous in breath. Notwithstanding there are reports of both children⁴⁷ and adults⁴⁸ who have undetectable levels of breath isoprene. Isoprene is highly volatile and hydrophobic ($\log P = 2.42$, $\text{bp} = 34\text{ }^{\circ}\text{C}$) with high tendency to partition into the gas phase ($\log P = -0.49$). A close correlation between blood and alveolar concentrations and a rapid response to a change in breathing and hemodynamic parameters may therefore be expected. A prompt reduction in end-tidal isoprene levels was observed in response to increased respiratory rate during physical exercise on an ergometer,⁴⁹ as well as during pulmonary recruitment on mechanically ventilated patients.^{37,39} In the current study, isoprene signal maximum showed an inverse proportionality to respiratory rate across the whole RR range reflecting a progressively quicker depletion of the airway compartment.

Acetone is also widely studied, due to its high relative abundance in breath, where it is believed to be released as by-

product of lipid degradation and ketogenesis. Compared to isoprene, acetone has a relatively high polarity and higher blood:air partition coefficient. For acetone the exchange mechanisms are more complex and involve interactions with the airway mucus layer. Our results show that acetone breath profiles are affected by a change in RR. This is in agreement with previous observations.^{37,49}

Aldehydes were studied as they appear to be consistently enriched in the breath of oesophago-gastric and colorectal cancer patients.^{41–43} In the case of oesophageal adenocarcinoma, a link has also been established between aldehyde accumulation and a deficiency in aldehyde detoxification.⁵⁰ When evaluating the influence of ventilator parameters, volatile C3–C7 aldehydes are all partially affected by a change in RR. In particular, a decrease in *maximum* is displayed by propanal, pentanal and hexanal: as observed for isoprene, it is likely that faster rates result in a quicker depletion of the airway compartments. This sensitivity to changes in RR decreases with the reduction in volatility. C8–C10 aldehydes are in comparison not affected: these compounds are the least

volatile and might respond less rapidly to a change in ventilation; moreover, for hydrophobic compounds other compartments (endothelial lining, muscle and fat tissue) might have a buffering action on breath VOC levels. For propanal and pentanal a statistically significant increase in maximum has been observed at the highest respiratory rate values. This is in agreement with recent studies carried out on ventilated patients⁵¹ and animal models,⁵² showing a positive correlation between breath pentanal and mechanical ventilation pressure, probably because of an increase in lipid peroxidation and oxidation stress.

Phenols (phenol, methyl-phenol and ethyl-phenol) and C2–C6 carboxylic acids have also been linked to oesophago-gastric cancer.^{41,42,44} None of these VOCs were significantly impacted by changes in respiratory parameters and this is not surprising considering these compounds are all polar, less volatile and have high blood : air partitioning coefficients. The only exception was acetic acid: as seen for other classes of compounds, faster airway depletion when RR is increased is probably favoured by a higher volatility. Since acetic acid has a high blood : air partitioning coefficient, exchanges are likely taking place in the airways and not at the alveolar level.

Propofol was also monitored during the experiments due to its relevance for surgical procedures. At the moment, no method is available for online propofol monitoring: the possibility to measure propofol in breath in real time has already been shown and propofol concentrations in blood, blood headspace and breath are correlated.³⁸ The fact that rapid modifications in ventilation parameters has no short-term effects on breath propofol levels would appear to support further research in to the use of breath analysis for propofol monitoring during surgery.

A limitation of this work resides in the choice of one spectrum s^{-1} as PTR-ToF-MS acquisition speed: a quicker acquisition speed might have provided better definition and more accurate parameter estimation, even though at the expense of sensitivity. It therefore remains unclear whether variation in VOC primarily in response to increasing RR is as a consequence of a true physiological effect relation to their partition between the airways and breath or alternatively as result of limitation in settings. The fact that findings obtained on isoprene and acetone agree with previous findings supports the validity of our approach.

Whilst RR and TV were carefully controlled during this study we did not record exact minute ventilation under experimental conditions. Discrepancy between ventilator setting and the ventilation delivered may have existed. Small sample size and the limited number of VOCs that could be assessed are other acknowledge limitation of this work. Finally, it remains uncertain whether these findings would be the same in situations where breath samples are collected off-line and what effect if any prior breathing pattern may have.

In conclusion, findings presented herein identify that for selected VOC variation in respiratory parameters, principally respiratory rate, can have a significant impact on the levels at which they are detected in breath. Whilst acknowledging that

it is not a requirement for all exhaled VOCs, it would nevertheless appear prudent to advocate greater standardisation for breath sampling in future research. Subjects should avoid strenuous activity, be rested prior to sampling and breathe slowly with a resting tidal volume. In awake patients, this could be achieved with the aid of visual or audible cues, such as a metronome.
