## Electrochemical conversion of lignin to short-chain carboxylic acids†

Shirong Sun,<sup>a,c</sup> Xueqing Qiu,<sup>\*a,c</sup> Shuhua Hao,<sup>a</sup> Sabarinathan Ravichandran,<sup>a</sup> Jinliang Song<sup>a</sup> and Wenli Zhang<sup>a,b,c</sup>

Lignin valorization is a challenge for chemical and materials scientists due to its complex molecular structure and intra- and inter-molecular assembly. Although catalytic conversion of lignin into small aromatic organic molecules has been widely investigated, it faces the problems of low selectivity and complex products. Herein, we report a direct electrochemical conversion method for the selective oxidation of industrial lignin to produce short-chain carboxylic acids (SCCAs) with a wide range of concentrations. In an electrolytic cell, lignin is chemically converted to SCCAs by H<sub>2</sub>O<sub>2</sub> with titanium silicate-1 (TS-1) as a catalyst. H<sub>2</sub>O<sub>2</sub> is generated *in situ* by the recombination of H<sup>+</sup> and HO<sub>2</sub><sup>-</sup> in a three-compartment cell by separately introducing hydrogen (H<sub>2</sub>) and oxygen (O<sub>2</sub>) as the sources of protons and HO<sub>2</sub><sup>-</sup> into the anode and cathode compartments. We have achieved a record-high concentration of SCCAs up to 109.8 mg mL<sup>-1</sup> through the catalytic depolymerization of lignin. A high concentration of SCCAs of 80.1 mg mL<sup>-1</sup> could also be achieved at a cell voltage of 2.13 V by coupling the 2e<sup>-</sup>-ORR and water oxidation using air and 1 M aqueous H<sub>2</sub>SO<sub>4</sub> solution as feedstocks. Our approach could eliminate the additional economic consumption and environmental hazards caused by the transportation and storage of commercially concentrated and stabilized H<sub>2</sub>O<sub>2</sub>. Aside from the SCCAs produced in this process, the formation of new carboxyl groups in the lignin residue during the oxidation reaction greatly broadens the application potential of industrial lignin.

## Introduction

Carboxylic acids are a class of essential chemicals widely used in materials, pharmaceuticals, food preservation, cosmetics, pesticides, and other manufactured chemicals, due to the special properties of their carboxylic group (acidity, polarity, surface properties, *etc.*).<sup>1,2</sup> Most of the carboxylic acids are produced through tandem oxidation processes of petrochemical feedstocks or biological fermentation of food resources.<sup>3</sup> The use of waste or renewable biomass as feedstock can effectively reduce our dependence on non-renewable carbon resources.<sup>4-6</sup> Lignin, the second-most abundant renewable polymer, is currently mostly produced as waste in pulping and bioethanol industries and is commonly burned to produce energy.

Consequently, the use of some of the lignin resources as raw materials to convert them into high-value-added products can effectively enhance the value of industrial waste without affecting the energy balance of the pulping industry.<sup>7</sup>

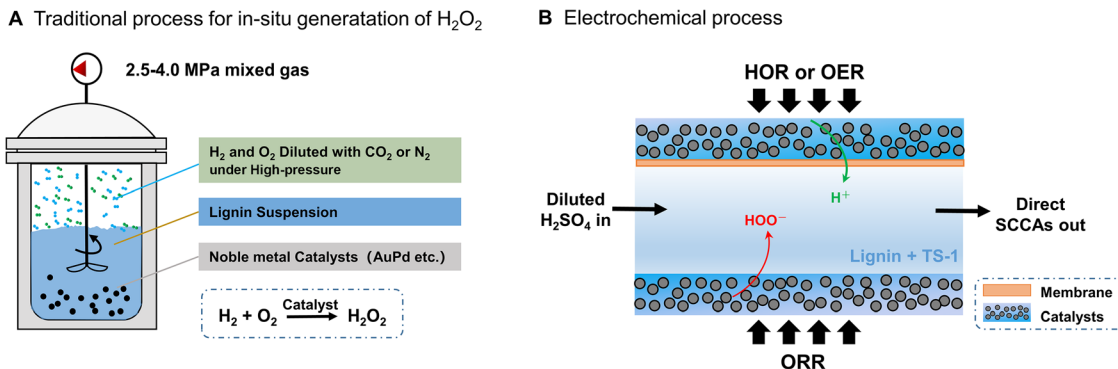

In plant cell walls, lignin is biosynthesized by coupling reactions between three primary precursors (Fig. S1†), *i.e.*, *p*-coumaryl (4-hydroxycinnamyl), coniferyl (4-hydroxy-3-methoxycinnamyl), and sinapyl (4-hydroxy-3,5-dimethoxycinnamyl) alcohols.<sup>8,9</sup> The heterogeneous and complex structural characteristics of lignin, including C–O bonds (β-O-4, α-O-4, α-O-γ, 4-O-5), C–C bonds (β-5, β-β, β-1, 5-5), a complex three-dimensional configuration and intra- and inter-molecular π–π interactions, make it difficult to generate products with regular structures.<sup>10-12</sup> The highly selective conversion of lignin becomes a recognized challenge, although various processes were developed, including acid/base catalysis,<sup>13</sup> enzymatic hydrolysis,<sup>14</sup> pyrolysis (thermolysis),<sup>15,16</sup> oxidation,<sup>17</sup> reduction (hydrogenolysis),<sup>18</sup> *etc.* Among these widely investigated methods, oxidation has been the most commonly used lignin depolymerization method, which is technically employed in the modern pulp bleaching processes.<sup>19</sup> Simultaneously, carboxylic acids, phenolic compounds, and furan and benzene compounds are produced in different bleaching stages of pulp treatment. These generated compounds are usually considered

**Fig. 1** Schematic illustration of the two different methods for producing short-chain carboxylic acids (SCCAs) from lignin using *in situ* generated H<sub>2</sub>O<sub>2</sub>. (A) Traditional direct synthesis of H<sub>2</sub>O<sub>2</sub> with diluted H<sub>2</sub> and O<sub>2</sub> gases and noble-metal catalysts (e.g., AuPd alloy) for lignin conversion. Alcohols, such as methanol and *t*-BuOH, were chosen as co-solvents for enhancing the solubility of H<sub>2</sub>. Sophisticated catalyst structural design was considered to prevent the degradation of *in situ* generated H<sub>2</sub>O<sub>2</sub>. (B) Direct electrochemical synthesis of H<sub>2</sub>O<sub>2</sub> with pure H<sub>2</sub> and O<sub>2</sub> introduced into the anode and cathode compartments separately. Diluted H<sub>2</sub>SO<sub>4</sub> was chosen as the lignin dispersion solvent and product carrier. A cation exchange membrane was used at the anode side, and a PTFE membrane was used as a liquid barrier at the cathode side. The catalysts were dispersed on a gas diffusion layer (GDL). The produced short-chain carboxylic acids (SCCAs) were collected directly from the three-compartment cell.

to be industrial waste, bringing a series of environmental problems, although in-depth basic research on lignin oxidation was carried out and convincing research results were obtained.<sup>7,20,21</sup> Therefore, the development and application of new technological processes for lignin conversion to achieve industrial-scale production of lignin-derived chemicals have stimulated the interest of researchers.<sup>22,23</sup>

Oxidation reactions can not only weaken the stacking force of  $\pi$ - $\pi$  interactions but also form hydroxyl and carboxyl groups by inserting oxygen functional groups into lignin side-chains and/or aromatic rings, becoming some of the most potential methods for the preparation of lignin-derived chemicals,<sup>24-26</sup> especially chemicals containing carboxyl groups. In this context, the most studied oxidants in lignin oxidation are molecular oxygen, KMnO<sub>4</sub>, nitrobenzene, metal oxides, and hydrogen peroxide (H<sub>2</sub>O<sub>2</sub>). Among these oxidants, the H<sub>2</sub>O<sub>2</sub> oxidation of lignin is highly promising since water is the only product of H<sub>2</sub>O<sub>2</sub> after the reaction, and no heteroatoms are introduced into the low molecular-weight organics.<sup>25-27</sup> This avoids the problems of complex post-treatment in industrial applications. In the current pulp bleaching industry, H<sub>2</sub>O<sub>2</sub> is a commonly used bleaching agent that can remove lignin from unbleached pulp with high selectivity.<sup>28</sup> The significant decrease in pH during H<sub>2</sub>O<sub>2</sub> bleaching proves the formation of a large amount of carboxyl-containing products.<sup>29</sup> In addition, industrial lignin resources including alkaline lignin and enzymatic hydrolysis lignin have been utilized for the preparation of short-chain carboxylic acids (SCCAs) by H<sub>2</sub>O<sub>2</sub> oxidation,<sup>30,31</sup> confirming that lignin is an excellent source candidate for the preparation of SCCAs. However, H<sub>2</sub>O<sub>2</sub> is currently produced through the anthraquinone process with high energy consumption and waste production.<sup>32-34</sup> The H<sub>2</sub>O<sub>2</sub> concentration produced by this conventional method is only 1-2% by weight, and energy-intensive concentration and complex purification processes are necessary to produce a marketable commodity.<sup>34</sup>

In addition, harsh storage and transportation conditions increase application costs due to the unstable and hazardous characteristics of highly concentrated H<sub>2</sub>O<sub>2</sub> solutions.

The direct catalytic synthesis process of H<sub>2</sub>O<sub>2</sub> using hydrogen (H<sub>2</sub>) and oxygen (O<sub>2</sub>) provides a new route in small-scale H<sub>2</sub>O<sub>2</sub> applications (Fig. 1A). Catalysts such as gold-palladium (AuPd) and palladium-tin (PdSn) have been developed for such reactions with high selectivity (>95%) for *in situ* H<sub>2</sub>O<sub>2</sub> generation.<sup>35,36</sup> Nevertheless, the flammability of high-pressure H<sub>2</sub> and O<sub>2</sub> mixtures is a disadvantage that necessitates that the mixture must be diluted with N<sub>2</sub> or CO<sub>2</sub>, which limits the synthesis of highly concentrated H<sub>2</sub>O<sub>2</sub>. In addition, methanol or *t*-butanol needs to be added to improve the solubility of H<sub>2</sub> to increase the rate of H<sub>2</sub>O<sub>2</sub> synthesis.<sup>37</sup> In the present work, an electrochemical process for the direct synthesis of H<sub>2</sub>O<sub>2</sub> is proposed to avoid the problems caused by the strategy of high-pressure production of H<sub>2</sub>O<sub>2</sub>. Pure H<sub>2</sub> and O<sub>2</sub> can be safely introduced separately into anode and cathode compartments to achieve the *in situ* synthesis of H<sub>2</sub>O<sub>2</sub> at various concentrations by coupling the 2e<sup>-</sup> O<sub>2</sub> reduction reaction (2e<sup>-</sup>-ORR) and the H<sub>2</sub> oxidation reaction (HOR) (Fig. 1B). The direct electrochemical formation of H<sub>2</sub>O<sub>2</sub> in such a three-compartment cell reduces the cost of transportation and storage of concentrated H<sub>2</sub>O<sub>2</sub>, as well as the risk associated with high-pressure equipment,<sup>36,38</sup> and becomes a potential process for industrial application including lignin conversion.

## Results and discussion

### Reaction procedures for electrochemical production of short-chain carboxylic acids

In our designed direct-electrochemical lignin conversion device, a state-of-the-art platinum-carbon (Pt/C) catalyst was chosen for the HOR to convert H<sub>2</sub> to H<sup>+</sup> with low overpoten-

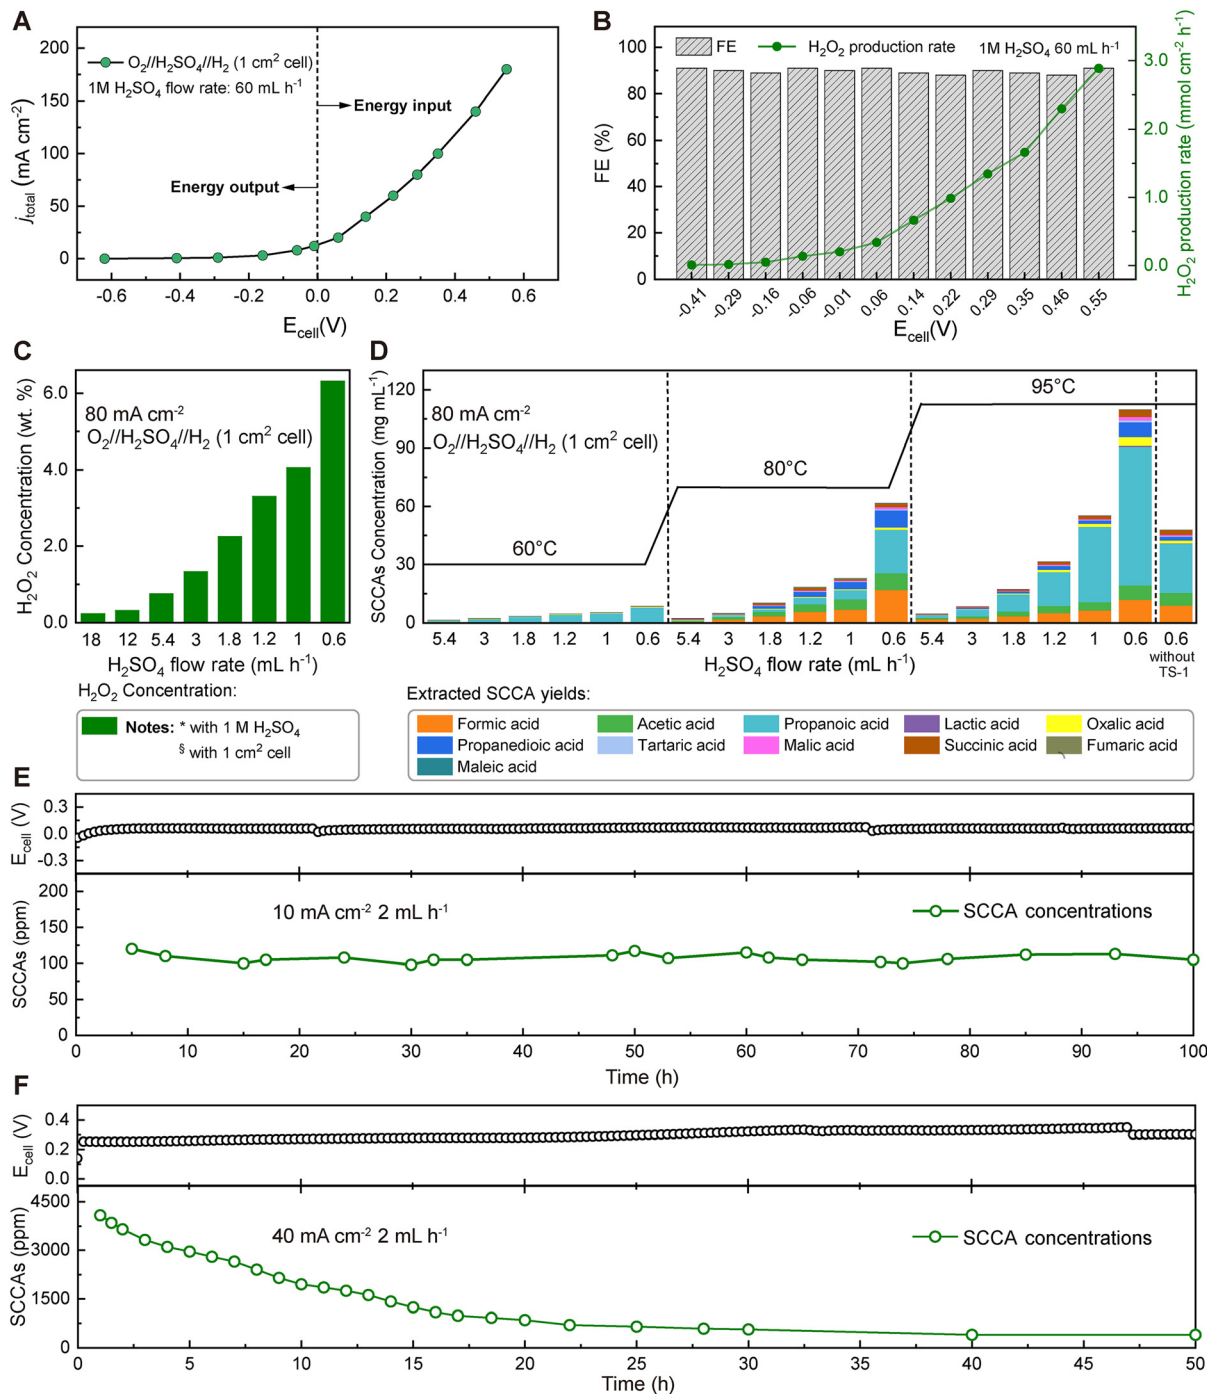

tials on the anode side. For the cathode, the research on electrocatalysts with high selectivity for the  $2e^-$ -ORR to  $H_2O_2$  is much less explored than that for the  $4e^-$ -ORR to water.<sup>39</sup> To meet the needs of industrial applications, surface-oxidized carbon black (O-CB) was applied as the cathode catalyst for the selective  $2e^-$ -ORR, because of its low cost, high selectivity, and high faradaic efficiencies (FEs) as described in the ESI (Fig. S2–S4†).<sup>40,41</sup> This single-step process could overcome the challenges of the traditional  $H_2O_2$  application in lignin oxidation, using a three-compartment cell, as a mature lignin conversion method. Fig. 2A shows the current–voltage ( $I$ – $V$ ) curve of the three-compartment cell with O-CB and Pt/C as electrocatalysts at the cathode and anode compartments, respectively. Pure  $H_2$  and  $O_2$  gases were directly introduced without any dilution treatments, and a 1 M aqueous  $H_2SO_4$  solution with a fixed flow rate of  $60\text{ mL h}^{-1}$  continuously flowed through the electrolytic cell with an electrode geometric size of  $1\text{ cm}^2$ . At a current of  $10\text{ mA cm}^{-2}$ ,  $H_2O_2$  can be synthesized *in situ* at a rate of  $0.20\text{ mmol cm}^{-2}\text{ h}^{-1}$  at  $-0.01\text{ V}$  without external energy input and even output electricity. The selectivity for  $H_2O_2$  generation was always higher than 90% over the entire voltage range (Fig. 2B). Different concentrations of  $H_2O_2$  could be obtained by adjusting the flow rate of the  $H_2SO_4$  solution (Fig. 2C). For efficient catalytic conversion of lignin with *in situ*-generated  $H_2O_2$ , titanium silicate-1 (TS-1) was chosen as the catalyst to enhance the oxidation activity by promoting the formation of hydroxyl and superoxide radicals.<sup>42</sup> Although many titanium-based catalysts have been developed for the catalytic oxidation process with  $H_2O_2$ , TS-1 is still considered the industrial standard catalyst for reactions of  $H_2O_2$  applications.<sup>43,44</sup> The morphological characterization of TS-1 zeolites was observed with SEM (Fig. S5†), and the powder XRD pattern indicates the presence of an ordered orthorhombic, MFI topology TS-1 framework (Fig. S6†).

Through this industrially available route, enzymatic hydrolysis lignin and commercial TS-1 (10 wt% based on lignin) were mixed and loaded into an O-CB// $H_2SO_4$ //Pt/C cell for *in situ*  $H_2O_2$  oxidation treatment. We observed a correlation between the reaction conditions (*i.e.*, temperature and  $H_2SO_4$  flow rates) and catalytic performance toward the direct conversion of lignin to SCCAs (Fig. 2D). Concerning the temperature conditions, the concentration of SCCAs significantly increased from  $60\text{ }^\circ\text{C}$  to  $95\text{ }^\circ\text{C}$  under different  $H_2SO_4$  flow rates. Likewise, concentrations of SCCAs significantly increased with decreasing  $H_2SO_4$  flow rates due to the increased concentration of the *in situ* generated  $H_2O_2$ , with the highest concentration of SCCAs being up to  $109.8\text{ mg mL}^{-1}$  (32.9 wt%, based on the weight of the initial lignin). The results indicate that the reactivity of the lignin conversion reaction was extremely sensitive to temperature and the concentration of  $H_2O_2$ . Moreover, catalyzed and non-catalyzed reactions were compared at an  $H_2SO_4$  flow rate of  $0.6\text{ mL h}^{-1}$  and  $95\text{ }^\circ\text{C}$ , confirming that the TS-1 catalyst improved the conversion efficiency of lignin to SCCAs with almost twice the concentration obtained without the addition of TS-1. The microporosity and hydrophobicity of the TS-1 catalyst, as well as the presence of titanium atoms, can

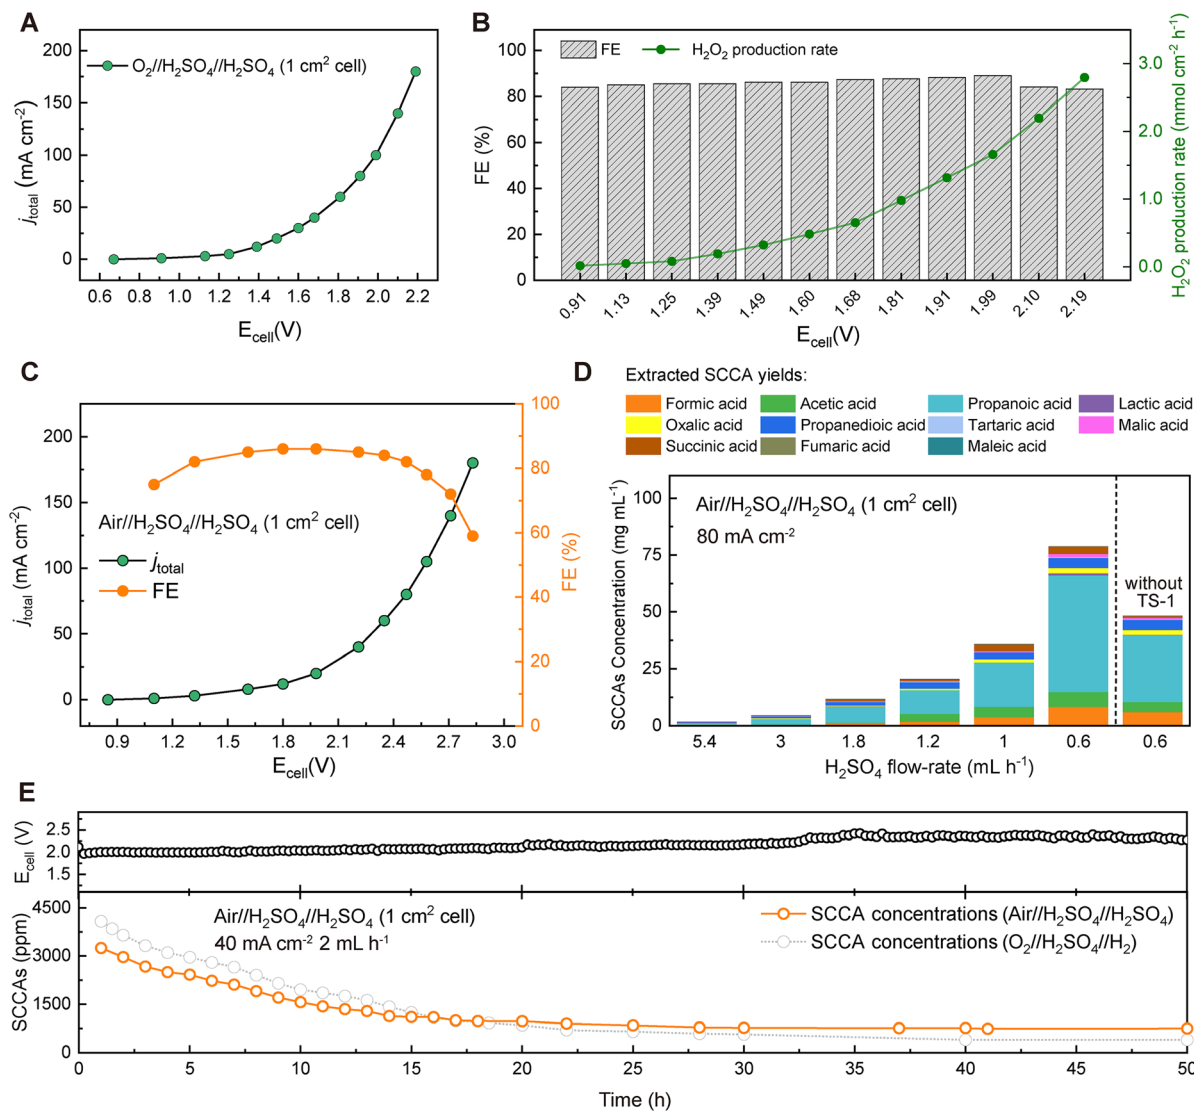

enhance the  $H_2O_2$  reaction performance by reducing the electron density of the O–O bond, making it susceptible to nucleophilic attack on lignin by  $H_2O_2$ -derived radicals.<sup>30,45</sup> The main short-chain carboxylic acid products include four monocarboxylic acids (MCAs), such as formic acid, acetic acid, propionic acid, and lactic acid, and seven dicarboxylic acids (DCAs), such as oxalic acid, propanedioic acid, tartaric acid, malic acid, succinic acid, fumaric acid and maleic acid. Among all products of SCCAs, the contents of formic acid, acetic acid, and propionic acid accounted for more than 80% of all products, especially propionic acid exceeded 60% of the total product content. Our device could continuously output  $\sim 100\text{ ppm}$  SCCA solution in a 100 hour test at a fixed flow rate of  $2\text{ mL h}^{-1}$  and a cell voltage of  $\sim 0\text{ V}$  without external energy input (Fig. 2E). Compared with traditionally used commercial  $H_2O_2$  produced by the anthraquinone process, the electrochemical *in situ*  $H_2O_2$  production method for biomass refinery is safe for human and environmental health. The method eliminates the need for transporting and storing hazardous bulk  $H_2O_2$ . A long-term operation test was also conducted for direct conversion of lignin at a cell current density and  $H_2SO_4$  flow rate of  $40\text{ mA cm}^{-2}$  and  $2\text{ mL h}^{-1}$ , and the device operated stably and continuously output SCCAs with the concentration decreasing over time from  $\sim 4200\text{ ppm}$  to  $\sim 500\text{ ppm}$  during 50 hours of operation until the lignin could not be further oxidized (Fig. 2F).

### Simulation of industrial production of short-chain carboxylic acids

To establish the industrial viability, we also used the reaction of water oxidation to  $O_2$  to release  $H^+$  instead of the HOR at the anode side using a commercial  $IrO_2$  electrode to simulate the conditions of no  $H_2$  supply in the industrial production process. 1 M  $H_2SO_4$  solution was circulated at a flow rate of  $30\text{ mL h}^{-1}$  on the anode side to reduce ionic resistance, and no SCCAs entered the  $H_2SO_4$  solution circulated at the anode side due to the blocking of the CEM membrane. A high  $H_2O_2$  production rate of  $2.79\text{ mmol cm}^{-2}\text{ h}^{-1}$  could be obtained at a cell voltage of 2.19 V in an O-CB// $H_2SO_4$ // $IrO_2$  cell (Fig. 3A and B). The selectivity for  $H_2O_2$  production was always higher than 80% (Fig. 3B), which was just slightly lower than that achieved with the O-CB// $H_2SO_4$ //Pt/C cell with pure  $H_2$  and  $O_2$ . Considering the more stringent conditions, the use of air instead of  $O_2$  also enabled *in situ* synthesis of  $H_2O_2$ , albeit at a higher voltage than when pure  $O_2$  was introduced (Fig. 3C). As the flow rate of the  $H_2SO_4$  solution that flowed through the cell decreased, the concentration of the output SCCAs increased significantly (Fig. 3D). A high concentration of SCCAs of  $80.1\text{ mg mL}^{-1}$  could be observed at an  $H_2SO_4$  flow rate of  $0.6\text{ mL h}^{-1}$ . A 50 hour stability test for continuous generation of SCCAs confirmed that lignin conversion could also be achieved when only air and  $H_2SO_4$  solutions were applied (Fig. 3E). The concentration of SCCAs decreased from  $\sim 3300\text{ ppm}$  to  $\sim 600\text{ ppm}$  in this long-term test, which could also enable the direct conversion of lignin to SCCAs.

**Fig. 2** Direct electrochemical production of short-chain carboxylic acids (SCCAs) from lignin using pure H<sub>2</sub> and O<sub>2</sub>. (A)  $I$ - $V$  curve for an O<sub>2</sub>//H<sub>2</sub>SO<sub>4</sub>//H<sub>2</sub> flow cell (1 cm<sup>2</sup>) in which Pt/C was chosen as the catalyst at the anode side, and oxygen-doped carbon black (O-CB) was selected as the catalyst at the cathode side. (B) The FEs and H<sub>2</sub>O<sub>2</sub> production rates at different voltage potentials. (C) H<sub>2</sub>O<sub>2</sub> production concentrations at an overall current density of 80 mA cm<sup>-2</sup> and different diluted H<sub>2</sub>SO<sub>4</sub> flow rates. (D) SCCA concentrations at different H<sub>2</sub>SO<sub>4</sub> flow rates and temperatures at a fixed current density of 80 mA cm<sup>-2</sup>. The SCCAs were collected in the first hour under different conditions. (E) The long-term operation test of SCCA production with concentrations of around 100 ppm at a fixed current density of 10 mA cm<sup>-2</sup> with negligible energy input. (F) Stability test for the continuous production of SCCAs at a fixed current density of 40 mA cm<sup>-2</sup>. The concentration of SCCAs gradually decreased with reaction time, indicating that lignin continued to degrade in this long-term test. The structures of the residues at 10 h and 50 h are elucidated in detail in subsequent texts. The 1 M diluted H<sub>2</sub>SO<sub>4</sub> flow rate was 2 mL h<sup>-1</sup> in the long-term tests shown in (E) and (F) at the reaction temperature of 80 °C.

**Fig. 3** Direct electrochemical production of short-chain carboxylic acids (SCCAs) from lignin by coupling the 2e<sup>-</sup>-ORR and water oxidation. (A) *I*-*V* curve of the O-CB//H<sub>2</sub>SO<sub>4</sub>//IrO<sub>2</sub> cell in which 1 M H<sub>2</sub>SO<sub>4</sub> solution was circulated at the anode side (30 mL h<sup>-1</sup>) for improving the ionic conductivity, and H<sub>2</sub>O was oxidized to form O<sub>2</sub> and protons. The flow rate of 1 M H<sub>2</sub>SO<sub>4</sub> solution flowing through the cell was 60 mL h<sup>-1</sup>. (B) The FEs and H<sub>2</sub>O<sub>2</sub> production rates at different voltage potentials of the O<sub>2</sub>//H<sub>2</sub>SO<sub>4</sub>//H<sub>2</sub>SO<sub>4</sub> cell. (C) *I*-*V* curve and FEs of the O-CB//H<sub>2</sub>SO<sub>4</sub>//IrO<sub>2</sub> cell when O<sub>2</sub> was replaced with air. (D) SCCA concentrations at different H<sub>2</sub>SO<sub>4</sub> flow rates flowing through the cell. A fixed current density of 80 mA cm<sup>-2</sup> and temperature of 95 °C were chosen with air and 1 M H<sub>2</sub>SO<sub>4</sub> solution as cathode and anode feedstock, respectively, in the O-CB//H<sub>2</sub>SO<sub>4</sub>//IrO<sub>2</sub> cell. The SCCAs were collected at different H<sub>2</sub>SO<sub>4</sub> flow rates flowing through the cell in the first hour. (E) Stability test for continuous production of SCCAs at a fixed current density of 40 mA cm<sup>-2</sup> using the O-CB//H<sub>2</sub>SO<sub>4</sub>//IrO<sub>2</sub> cell by the 2e<sup>-</sup>-ORR and water oxidation at the reaction temperature of 80 °C.

### Mechanism studies

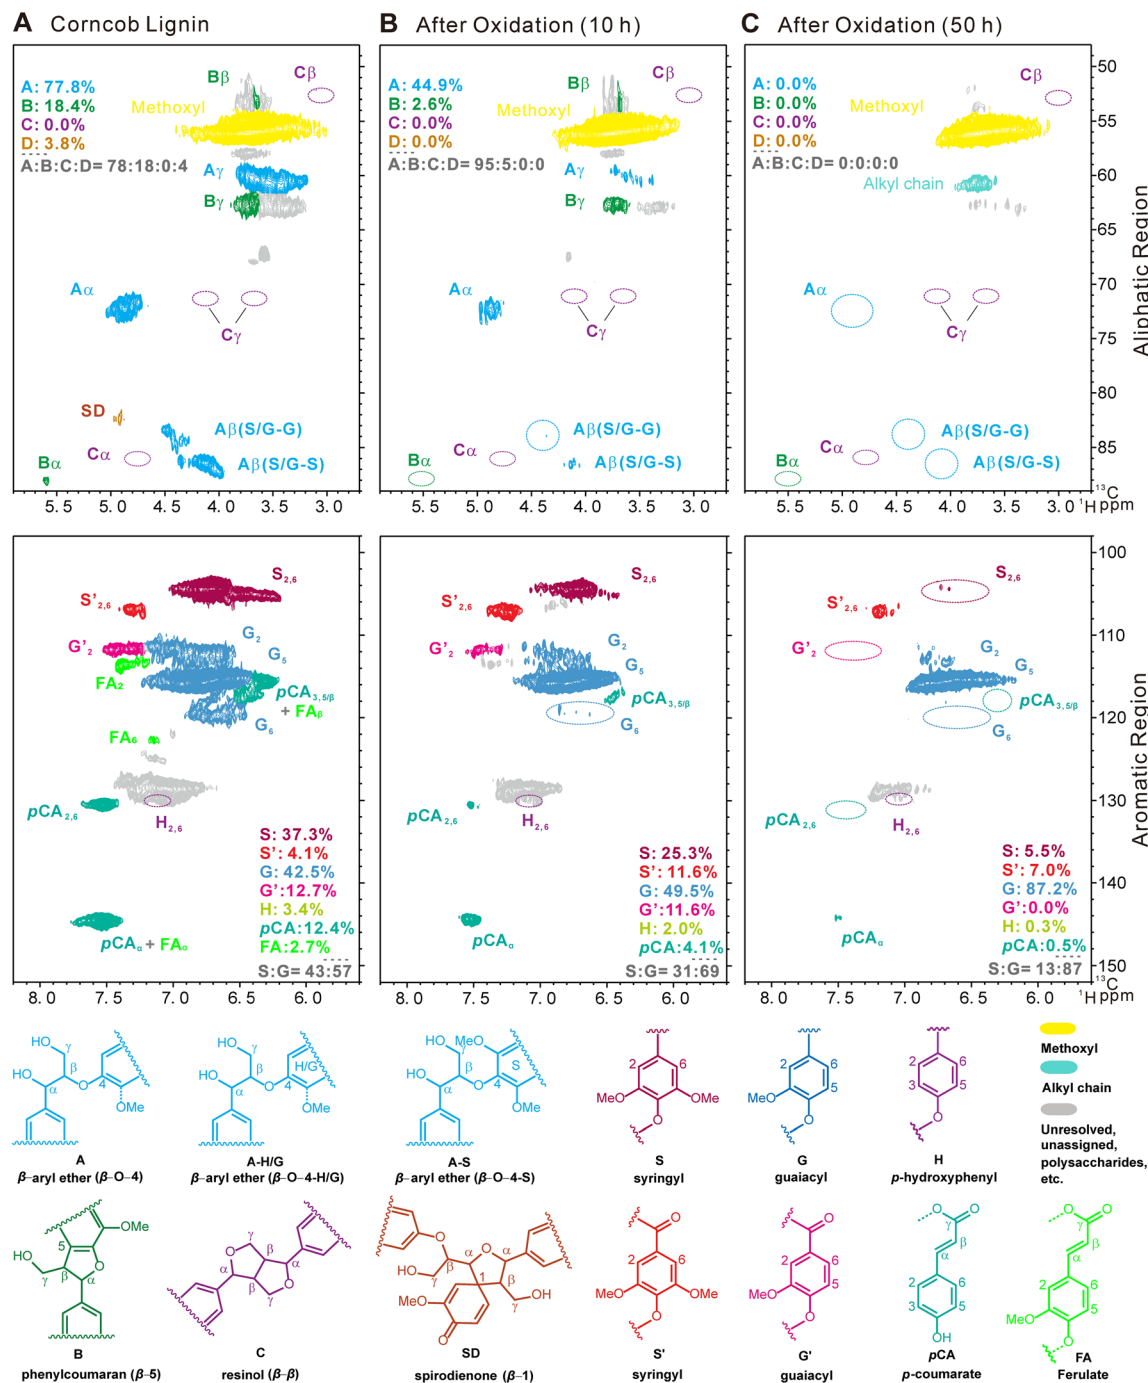

The potential mechanism was investigated using guaiacol and 1,2-dimethoxy benzene as monomeric models, and several arylglycerol-β-aryl ether (β-O-4 structure) lignin models with guaiacyl (G) and/or syringyl (S) nuclei, *erythro* or *threo* stereostructures, with or without terminal hydroxyl groups as dimeric models, respectively. The synthetic route to the dimeric model compounds, the quantitative method of the *erythro* and *threo* stereoisomers, and the structures of model compounds used for mechanism studies are listed in the ESI (Fig. S7–S9†). TS-1-catalyzed H<sub>2</sub>O<sub>2</sub> oxidation of monomeric models guaiacol and 1,2-

dimethoxy benzene was found to generate different DCAs, mainly including malic acid, succinic acid, tartaric acid, etc., with total yields of 8.7 and 8.2 wt% at the conversion yields of 32 and 25 wt%, respectively. In the oxidation of the non-phenolic dimeric lignin model compounds, not only different MCAs (7.1 wt%) containing formic acid, acetic acid, and lactic acid but also different DCAs (20.5 wt%) containing propanedioic acid, tartaric acid, malic acid, succinic acid, fumaric acid and maleic acid were detected at the conversion yield of 80 wt%. In the oxidation of the phenolic dimeric lignin model compounds, different MCAs (11.1 wt%) and DCAs (18.5 wt%) were detected at the conversion yield of 95 wt%. A relatively high amount of

propionic acid was detected only when the lignin dimeric model contained terminal phenolic hydroxyl groups (2.5 wt%). These results pointed out that MCAs were mainly derived from the side-chain oxidation of lignin, while DCAs were primarily derived from the oxidative ring-opening reaction of the aromatic rings, although oxalic acid, lactic acid, malonic acid, *etc.*, may also be derived from the oxidation of aromatic rings. The struc-

ture of the lignin models with or without terminal hydroxyl groups affected the distribution of SCCA product yields, possibly due to the easy nucleophilic attack of the hydroxyl group by hydroxyl and superoxide radicals followed by the electron rearrangement on aromatic rings.

Fig. 4 shows the 2D HSQC NMR spectra of industrial enzymatic hydrolysis lignin (typical industrial lignin isolated from

**Fig. 4** Partial 2D HSQC NMR spectra of an industrial enzymatic hydrolysis corncob lignin (in DMSO- $d_6$ ) before and after electrochemical conversion. (A) Original enzymatic hydrolysis corncob lignin. (B) The residual lignin resulting from the electrochemical treatment for 10 h and (C) 50 h in an  $O_2/H_2SO_4/H_2$  flow cell (1 cm<sup>2</sup>). The contour areas are color-coded to the corresponding structures and integrated to calculate the interunit linkage (aliphatic regions) and aromatic unit (aromatic regions) distributions.

Fig. 5 A schematic diagram of the proposed lignin oxidation mechanism by H<sub>2</sub>O<sub>2</sub> to directly produce SCCAs.

corn cob with **S**, **G** and **H** nuclei and C–O and C–C side-chain structures) before and after the direct conversion treatment of the long-term test in an O-CB//H<sub>2</sub>SO<sub>4</sub>//Pt/C cell. The aliphatic regions (top panels of Fig. 4A–C) revealed that 32.9% of the β-ether linkages were cleaved at 10 h, and all were cleaved during the 50 hour treatment. The phenomenon was also observed in phenylcoumaran (β-5 linkage) and spirodienone (β-1 linkage) structures. The aromatic regions (middle panels of Fig. 4A–C) indicated that the assignment of syringyl nuclei (**S**) decreased with the reaction of 10 h and disappeared at 50 h. The aromatic regions also revealed that the **S** unit was oxidized to the benzylic ketone analogue **S'** unit, although the content of the **S'** unit also gradually decreased during the continuous processing. Overall, this preliminary study demonstrates that the electrochemical *in situ* generation of H<sub>2</sub>O<sub>2</sub> in combination with the TS-1 catalyzed direct conversion of lignin generates free radicals that can simultaneously nucleophilically attack the side chain and aromatic ring of lignin to achieve efficient conversion of lignin to SCCAs. At the same time, the polymerization of lignin occurred, which was manifested by the disappearance of G<sub>2</sub> and G<sub>6</sub> signals and the presence of the G<sub>5</sub> signal. The content of *p*-coumaric acid (*p*CA), a typical structure in herbaceous plants, decreased significantly and became one of the main source structures of lignin oxidation to produce SCCAs, especially propionic acid.<sup>46,47</sup> The carboxyl group content in the lignin residues was significantly increased to 2.52 mmol g<sup>-1</sup> (10 h) and 2.74 mmol g<sup>-1</sup> (50 h), from the 0.46 mmol g<sup>-1</sup> of the raw corn cob lignin measured by aqueous potentiometric titration using an automatic potentiometric titrator (809 Titrando, Metrohm Corp., Switzerland), which greatly broadened the feasibility of lignin applications.<sup>48,49</sup>

## Conclusions

In summary, we have identified a highly effective electrochemical method for direct conversion of lignin to high concentration SCCAs by the *in situ* generated H<sub>2</sub>O<sub>2</sub>. Radicals derived from H<sub>2</sub>O<sub>2</sub> can selectively attack the lignin side chain to break the conjugated C3-side structures and the lignin aromatic

ring part to achieve a ring-opening reaction of the phenylpropane structure to generate the corresponding SCCAs (Fig. 5). The optimized catalyst system that simulated industrial conditions could perform using only air and H<sub>2</sub>SO<sub>4</sub> solution as feedstocks and was potentially suitable for large-scale industrial applications. The prepared SCCAs could be utilized in organic reagents, esterification agents, plasticizers, preservatives, pharmaceutical intermediates, and other high-value applications. This approach could form a basic method for extended chemical transformations that depends on *in situ* generated H<sub>2</sub>O<sub>2</sub> and TS-1.

## Experimental

### Materials

The enzymatic hydrolysis lignin (EHL) derived from corn cob was provided by Shandong Longlive Biotechnology Co., Ltd. The EHL was purified by sequential alkali dissolution and acid precipitation treatment before use. TS-1 was purchased from Rhawn Corporation. All commercially available chemicals and solvents except those mentioned were purchased from Macklin and Aladdin Corporation and used as received unless stated otherwise. Deionized H<sub>2</sub>O was used in all the experiments.

### Synthesis of oxygen-doped carbon black (O-CB) catalysts

Oxygen-doped carbon black (O-CB) catalysts were prepared as described in a previous report.<sup>50</sup> In brief, 1.0 g of commercial carbon black (XC-72R, Cabot, USA) was added to 600 mL of 12 mol L<sup>-1</sup> HNO<sub>3</sub> and refluxed at 85 °C for 1 h, 3 h, 6 h, 9 h, and 12 h, respectively. After the slurries were cooled down to room temperature, they were centrifuged and washed with water until neutral pH values. Finally, the samples were dried at 70 °C in a vacuum oven. The functionalized carbon blacks were obtained with different surface oxygen doping levels.

### Rotation ring disk electrode (RRDE) test

The ORR activities of O-CB were measured using linear sweep voltammetry (LSV) with a rotation ring disk electrode (RRDE)

in a typical three-electrode system (PINE Instrument, USA). To prepare the O-CB working electrode, 3.3 mg of O-CB was mixed with 10  $\mu\text{L}$  of Nafion 117 (dissolved in 1 mL of ethanol) to obtain a homogeneous catalyst slurry by ultrasonication. 6  $\mu\text{L}$  of the as-prepared catalyst slurry was pipetted on the rotating disk glassy carbon electrode with a  $0.1 \text{ mg cm}^{-2}$  mass loading. The O-CB cast electrode was vacuum dried before use. 0.1 M  $\text{Na}_2\text{SO}_4$  was saturated with high-purity  $\text{O}_2$  as an electrolyte. A continuous flow of  $\text{O}_2$  was used as a shielding gas for the electrolyte. A platinum wire and Ag/AgCl electrode were used as the counter and reference electrodes, respectively. All the potentials against Ag/AgCl were calculated by converting to the reversible hydrogen electrode (RHE) using the equation  $E(\text{vs. RHE}) = E(\text{vs. Ag/AgCl}) + 0.197 \text{ V} + 0.0591 \times \text{pH}$ . The  $\text{H}_2\text{O}_2$  selectivity was calculated using the following equation:  $\text{H}_2\text{O}_2(\%) = 200 \times (I_{\text{ring}}/N)/(I_{\text{disk}} + I_{\text{ring}}/N)$ , where  $I_{\text{ring}}$  and  $I_{\text{disk}}$  are the ring and disk currents, respectively, and  $N$  is the ring collection efficiency, determined to be 0.32 in a solution of 2 mM  $\text{K}_3\text{Fe}(\text{CN})_6$  and 0.1 M  $\text{KNO}_3$ .

### Electrochemical cell performance test

For the two-electrode cell for direct electrochemical production of  $\text{H}_2\text{O}_2$ , commercial Pt/C on a gas diffusion layer (GDL) ( $1 \text{ mg cm}^{-2}$ ) was used as the anode, and around  $0.5 \text{ mg cm}^{-2}$  O-CB loaded on a GDL was prepared as the cathode. Typically, 10 mg of O-CB was mixed with 0.5 mL of Nafion 117 solution (5% diluted in ethanol), then sonicated and pipetted onto the GDL and vacuum dried before use. For the  $\text{O}_2//\text{H}_2\text{SO}_4//\text{H}_2$  cell, 50 sccm of humidified  $\text{O}_2$  and  $\text{H}_2$  were introduced into the cathode and anode, respectively. A commercial  $\text{IrO}_2$  electrode was applied when the anode side was replaced with 1 M  $\text{H}_2\text{SO}_4$  solution circulating at a flow rate of  $30 \text{ mL h}^{-1}$ . The  $\text{O}_2$  gas was also replaced with air when pure  $\text{O}_2$  was not supplied for mimicking more severe  $\text{H}_2\text{O}_2$  production conditions. All electrochemical tests were performed with Admiral Instruments Squidstat<sup>TM</sup> Plus and Donghua DH7000 electrochemical workstations. Industrial lignin (200 mg) and TS-1 (10 wt% based on lignin) were mixed and loaded on the three-compartment cell for the direct electrochemical conversion of lignin. In the experiments to prepare SCCAs by direct electrochemical oxidation of lignin at different temperatures and  $\text{H}_2\text{SO}_4$  flow rates, the output SCCAs in the first hour were collected for quantification.

### Synthesis, characterization, and reaction of lignin model compounds

The dimeric compounds with  $\beta$ -aryl ether bonds were synthesized according to the method of Adler *et al.*<sup>51</sup> The detailed synthesis route is shown in Fig. S7.† The structure of compound (2-(2-methoxyphenoxy)-1-(3,4,5-trimethoxyphenyl)propane-1,3-diol) was identified by NMR, and the content of each isomer was quantified by the method described in the previous paper.<sup>52,53</sup> Degradation experiments of each model compound were performed with sealed bottles. The reaction conditions were as follows: 10 mg of the model compound, 30 mL of solvent containing 5 mL of 1,4-dioxane, 25 mL of

1 mol  $\text{L}^{-1}$   $\text{H}_2\text{SO}_4$  solution, and 1 mL of commercial  $\text{H}_2\text{O}_2$  (30 wt%) at a reaction temperature of 95  $^\circ\text{C}$ .

### $\text{H}_2\text{O}_2$ and SCCA concentration quantification and faradaic efficiency (FE) calculations

In a two-electrode cell, the produced concentration of  $\text{H}_2\text{O}_2$  was determined by redox titration with KI aqueous solution, according to the reported procedures.<sup>54,55</sup> The faradaic efficiency (FE) for  $\text{H}_2\text{O}_2$  production is calculated according to the following equation:

$$\text{FE} = \text{generated } \text{H}_2\text{O}_2(\text{mol L}^{-1}) \times 2 \times 96485(C \text{ mol L}^{-1}) \times \text{flow rate}(\text{mL s}^{-1})/j_{\text{total}}(\text{mA}) \times 100$$

The quantification of SCCAs was conducted with a high-performance liquid chromatography instrument (HPLC, Agilent 1260 Infinity II) equipped with an ultraviolet-visible (UV-Vis, 1260 VWD) absorption detector at 210 nm. In HPLC analyses, an HPLC column, Ultimate AQ-C18 (length: 250 mm, inner diameter: 4.6 mm, and particle size: 5.0  $\mu\text{m}$ , Welch, Shanghai, China), was used at an oven temperature of 30  $^\circ\text{C}$  with a solvent flow rate of  $0.7 \text{ mL min}^{-1}$ . 20 mM dibasic sodium phosphate solvent with a pH of 2.60 adjusted using phosphoric acid containing 1% methanol was used as mobile phase A. Methanol was used as mobile phase B. The solvent system used for quantification of SCCAs was run at a gradient A/B (v/v) of 100/0 for 9 min, from 100/0 to 50/50 within 11 min, and held for 5 min and equilibrated for 5 min.

### 2D heteronuclear single quantum coherence (HSQC) NMR analysis

For 2D heteronuclear single quantum coherence (HSQC) NMR analysis, 80–90 mg lignin in 0.6 mL of dimethyl sulfoxide- $d_6$  and 40  $\mu\text{L}$  of chromium(III) acetylacetonate (0.01 M) were added to an NMR tube. The 2D HSQC NMR characterization of each lignin sample was performed on a Bruker AVANCE III HD 600 MHz spectrometer equipped with a 5 mm BB probe. Sufficient amounts of scans consisting of 4096 by 256 points were collected.
