## Reaction of methionine with chlorine: kinetics, product formation, and potential use as a scavenger in chlorine dioxide-based systems†

Mischa Jütte, <sup>a</sup> Josephine Heyns,<sup>a</sup> Mohammad Sajjad Abdighahroudi, <sup>a</sup> Christoph Schüth<sup>bc</sup> and Holger V. Lutze <sup>\*acd</sup>

The present study investigates the reaction of methionine with free available chlorine (FAC) and estimates the usability of methionine as a selective scavenger for intrinsically formed FAC in chlorine dioxide (ClO<sub>2</sub>)-based reactions. It has been reported that ClO<sub>2</sub> forms chlorite and FAC in the reaction with phenolic compounds. However, for some reactive moieties such as reduced sulfur-containing compounds, no quantification of FAC could be carried out yet, due to the limitation of the current methods which arise from the high reactivity of these compounds with both ClO<sub>2</sub> and FAC. Methionine reacts fast with FAC ( $k_{app} = 6.8 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$  at pH 7), and very slow with ClO<sub>2</sub> ( $k_{app} = 10^{-2} \text{ M}^{-1} \text{ s}^{-1}$  at pH 7). Methionine sulfoxide and chloride are formed in equal parts in the reaction of methionine with FAC, as stable products. Hence the yield of methionine sulfoxide and chloride can principally be used to quantify intrinsically formed FAC. While the results for phenol were in accordance with the literature (50% chlorite and 50% FAC), hydroquinone and 1,4-dimethylpiperazine also resulted in methionine sulfoxide yields, even though no FAC formation has been reported for these compounds. It is possible that reactive organic intermediates are formed, which additionally causes methionine sulfoxide formation (e.g., semiquinone or phenoxy radicals). Based on this study, the FAC formation in the reaction of glutathione with ClO<sub>2</sub> can be confirmed and is expected to be 50%. However, since methionine sulfoxide can be formed by reactive organic intermediate species, quantitative statements should be handled with care.

### Water impact

This study showed that methionine can be used to scavenge intrinsically formed FAC in reactions of organic compounds with ClO<sub>2</sub>. This finding will increase the knowledge about ClO<sub>2</sub> reactions and thus help to improve ClO<sub>2</sub>-based water treatment.

## Introduction

Chlorine dioxide (ClO<sub>2</sub>) based oxidation is increasingly used in water treatment since it is less prone to form halogenated disinfection by-products (DBPs) compared to chlorine which forms DBPs such as trihalomethane (THM).<sup>1,2</sup> Indeed, ClO<sub>2</sub> shows less THM formation compared to chlorine.<sup>3</sup> However, it is proven that in its reactions with specific reactive moieties

(e.g., phenols) free available chlorine (FAC) is formed as a reaction product.<sup>4–8</sup> Although the most abundant reaction product is chlorite (ClO<sub>2</sub><sup>−</sup>), in the reaction with most phenolic moieties, FAC and ClO<sub>2</sub><sup>−</sup> are formed in 50% ratios each.<sup>4–8</sup> In the reaction with saturated nitrogen-containing heterocycles, ClO<sub>2</sub> is reported to react mainly *via* electron transfer, and nearly 100% ClO<sub>2</sub><sup>−</sup> is formed.<sup>9</sup> Other studies showed that ClO<sub>2</sub> could react with specific amino acids and form 50% FAC and 50% ClO<sub>2</sub><sup>−</sup>.<sup>7,10,11</sup> The fate of this intrinsically formed FAC has not been fully investigated yet. Intrinsically formed FAC may cause the formation of harmful DBPs in ClO<sub>2</sub> treatment. However, FAC as secondary oxidant might positively affect pollutant degradation and disinfection.<sup>12,13</sup> For instance, the reaction with phenols and amines, which are reactive moieties of a broad range of micropollutants, differs strongly between ClO<sub>2</sub> and FAC. While phenolic compounds react fast with ClO<sub>2</sub>,<sup>12</sup> they react slow with FAC.<sup>14</sup> On the other hand, FAC

reacts very fast with primary amines, which react slow with  $\text{ClO}_2$ . This synergy might allow to degrade a broader spectrum of pollutants during  $\text{ClO}_2$  based (waste)water treatment.<sup>4,12</sup>

The challenge of determining intrinsic FAC formation is to outcompete all other reactions that FAC might undergo in the corresponding reaction system (*cf.* reactivities of FAC).<sup>14</sup> This can only be done with a selective scavenger (for FAC reactions) which provides full scavenging of FAC without reacting with  $\text{ClO}_2$ . Different approaches have been used so far. One reported approach is the addition of ammonia as a selective scavenger.<sup>5</sup> Thereby, ammonia reacts several orders of magnitude faster with FAC than  $\text{ClO}_2$  ( $k_{\text{app}}(\text{FAC} + \text{NH}_3) = 1.3 \times 10^4 \text{ M}^{-1} \text{ s}^{-1}$  at pH 7,  $k_{\text{app}}(\text{ClO}_2 + \text{NH}_3) < 10^{-6} \text{ M}^{-1} \text{ s}^{-1}$  at pH 7)<sup>14,15</sup> and forms chloramine ( $\text{NH}_2\text{Cl}$ ), which can be quantitatively detected.<sup>5</sup> Terhalle *et al.*, used bromide ( $\text{Br}^-$ ) as FAC scavenger.  $\text{Br}^-$  reacts fast with FAC ( $k_{\text{app}} = 5.3 \times 10^3 \text{ M}^{-1} \text{ s}^{-1}$  at pH 7)<sup>14</sup> and forms free available bromine (FAB), which further reacts with phenol to form bromophenols and the quantification of intrinsic FAC was carried out by quantification of formed bromophenols.<sup>4</sup> Glycine has also been used as a selective scavenger.<sup>6–9</sup> Glycine reacts fast with FAC ( $k_{\text{app}} = 1.5 \times 10^5 \text{ M}^{-1} \text{ s}^{-1}$  at pH 7)<sup>14</sup> and slow with  $\text{ClO}_2$  ( $k_{\text{app}} < 10^{-5} \text{ M}^{-1} \text{ s}^{-1}$  at pH 7)<sup>15</sup> and is, therefore, a suitable scavenger for intrinsically formed FAC. The reaction of FAC with glycine forms chloro-glycine (Cl-Gly), which can be detected photometrically in the presence of iodide in excess<sup>16</sup> or with IC simultaneous to other chlorine species formed in the reaction (glycine method).<sup>17</sup> The sensitivity of the glycine method can be further increased by installing post column reaction using potassium iodide as reactant and ammonium molybdate as a catalyzer.<sup>17</sup> However, it has been shown that Cl-Gly can undergo follow-up reactions with intrinsically formed reactive species (*e.g.*, *ortho*-benzoquinone) which would result in a wrong interpretation of the FAC yields.<sup>8</sup>

All methods mentioned above have the drawback that the second-order reaction rate constant of FAC with the scavenging compound is the limiting factor. Thus, most sulfur-containing compounds can hardly be investigated in terms of FAC formation because the reaction rate of FAC with these sulfur-containing compounds is several orders of magnitude faster compared to the reaction rate of FAC with the aforementioned scavengers.<sup>14</sup> For full scavenging of FAC high scavenger-surpluses over the compound under study are required, which may result in undesired  $\text{ClO}_2$  scavenging. Ison *et al.* gave evidence that FAC might be formed in the reactions of cysteine and glutathione (GSH) with  $\text{ClO}_2$ .<sup>18</sup> However, the available FAC determination methods are not capable of quantifying the FAC yields in these reactions. This study investigates methionine as a novel scavenger for the determination of intrinsically formed FAC in the reaction of  $\text{ClO}_2$  with sulfur-containing compounds. The reaction rate for methionine with FAC is  $k_{\text{app}} = 6.8 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$  at pH 7 (ref. 14) and methionine has been reported to be unreactive toward  $\text{ClO}_2$  at pH 6.<sup>19</sup> A proposed pathway for the reaction of methionine shows that the reaction stoichiometry of FAC with methionine is 1 : 1 and yields 1 molecule of methionine sulfoxide (MSO) and one molecule of chloride ( $\text{Cl}^-$ ).<sup>14</sup>

## Material and methods

### Chemicals, instruments, & methods

The chemicals used in this study and their purpose of use are listed in Table S1† Table S2† provides an overview of the instruments used in this study. Finally, Tables S3 and S4† show the IC and LC method used for detection, respectively.

### Production of $\text{ClO}_2$ and FAC solutions

$\text{ClO}_2$  solutions were produced on-site by using the persulfate-chlorite method. Detailed information on the procedure is provided in literature.<sup>4</sup> Since  $\text{ClO}_2$  is an unstable and volatile oxidant, the concentration of the  $\text{ClO}_2$  stock solution needs to be measured before every experiment. This was carried out by direct absorption measurement at  $\lambda = 359 \text{ nm}$  ( $\epsilon_{359} = 1250 \text{ M}^{-1} \text{ s}^{-1}$ ).<sup>20</sup>  $\text{ClO}_2$  stock solutions were stored in the dark at 4 °C and were used until the concentration of  $\text{ClO}_2$  dropped below 80% of the initial concentration after production. Detailed information about the impurities of the stock solution can be found in previous work.<sup>8</sup>

FAC solutions were prepared daily before every experiment. A 15% FAC solution was 400-fold diluted in pure water and the FAC concentration was measured by direct absorption measurement at  $\lambda = 292 \text{ nm}$  ( $\epsilon_{292} = 350 \text{ M}^{-1} \text{ cm}^{-1}$ ) (note that the concentration is determined by measuring absorption of  $\text{OCl}^-$  thus, pH should be above 10 ( $\text{p}K_{\text{a}} = 7.54$ )).<sup>17</sup>

### Determination of reaction kinetics

The second-order reaction constant ( $k_{\text{app}}$ ) for the reaction of methionine with  $\text{ClO}_2$  has been determined by pseudo-first-order kinetics by monitoring the UV absorbance of  $\text{ClO}_2$  over time. Therefore, a reaction solution containing different concentrations of methionine and  $\text{ClO}_2$  was mixed in a 3 mL quartz cuvette (optical path length 1 cm), and the adsorption of  $\text{ClO}_2$  at  $\lambda = 359 \text{ nm}$  was monitored over time (data points were measured every 2 seconds for 30 minutes). Furthermore, the reaction solution contained 5 mM phosphate buffer to ensure a constant pH of 7.  $\text{ClO}_2$  was added with two different molar ratios towards methionine (1:10, and 1:100). All experiments were carried out in triplicates.

By plotting the  $\text{ClO}_2$  degradation as  $\ln([\text{ClO}_2]/[\text{ClO}_2]_0)$  over time, the pseudo-first-order rate constant ( $k_{\text{obs}}$ ) of the reaction can be calculated. The slope of this plot ( $k_{\text{obs}}$ ) needs to be divided by the initial concentration of the compounds in excess ( $[A]$ ), which gives the second-order reaction rate constant according to eqn (1).

$$k_{\text{app}} = \frac{k_{\text{obs}}}{[A]_0} \quad (1)$$

### Formation of chloride and MSO in methionine oxidation by FAC

The inorganic reaction products of the reaction of methionine with FAC have been determined *via* IC. Therefore, 100  $\mu\text{M}$  methionine solution reacted with different concentrations of FAC (20–100  $\mu\text{M}$ ) at pH 7. After a reaction time of 10 minutes, to ensure full turnover of FAC ( $k_{\text{app}}$  (FAC + methionine) =  $6.8 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ ),<sup>14</sup> the aliquots were transferred into IC vials (polypropylene (PP)) and measured with the IC method described in Table S3.† One has to take into account that the stock solution of FAC contains high impurities of  $\text{Cl}^-$ . Therefore, the determination of  $\text{Cl}^-$  impurities is necessary. For this purpose, identical FAC concentrations were dosed into a 10 mM glycine solution (further containing 5 mM phosphate buffer at pH 7) to scavenge all FAC species. The remaining  $\text{Cl}^-$  can be quantified and later subtracted from the measured  $\text{Cl}^-$  concentration in the reaction of methionine with FAC.

The formation of MSO as a reaction product was measured *via* LC–MS/MS, described in Table S4.† The formation of MSO was measured as the reaction product of methionine with FAC and calibrated with the commercially available standard. To determine the reaction products of methionine and FAC, different doses of FAC were added to 100  $\mu\text{M}$  methionine solution, buffered at pH 7. Formed MSO was quantified using a calibration based on external standards which were commercially available. All experiments were carried out in triplicates.

### Model compounds

To test the suitability of the developed method, four model compounds were chosen with different chlorine balances (sum of different chlorine species formed per consumed  $\text{ClO}_2$ ). While phenol is reported to show 50% FAC and 50%  $\text{ClO}_2^-$  formation,<sup>4,5</sup> 1,4-dimethylpiperazine (DMP) and hydroquinone have been observed to form 100%  $\text{ClO}_2^-$  in  $\text{ClO}_2$ -based reactions as inorganic by-products.<sup>6,9</sup> GSH was investigated as a sulfur-containing model compound.

Reaction solutions contained 100  $\mu\text{M}$  of the model compound, 1 mM methionine, and 5 mM phosphate buffer adjusted to pH 7.  $\text{ClO}_2$  was added in different doses (50, 100, and 200  $\mu\text{M}$ ). After a reaction time of 30 min, aliquots were transferred to LC (glass) and IC (PP) vials and were measured by IC and LC–MS/MS described in Tables S3 and S4.† All chlorine balances were determined in triplicates. For determination of FAC recovery a defined dose of FAC (100  $\mu\text{M}$ ) was added to an aliquot of the exact same reaction solutions which was used for  $\text{ClO}_2$  treatment. The FAC recovery rate was determined by the ratio of measured *vs.* added FAC. By this any matrix effects of the reaction solution could be observed/ruled out. Note, that is approach does not cover the interference by intrinsically formed species.<sup>8</sup>

### Follow-up reactions

To investigate the follow-up reactions of GSH with  $\text{ClO}_2^-$ , different GSH doses were dosed to 100  $\mu\text{M}$   $\text{ClO}_2^-$  in presence of 10 mM glycine at pH 7. The chlorine balance of these solutions were measured after 5 min, 24 hours, and 48 hours.

To investigate if formed  $\text{ClO}_2^-$  is causing MSO formation by reacting with methionine, a long-term monitoring experiment was conducted. Thereby 100  $\mu\text{M}$   $\text{ClO}_2^-$  and 100  $\mu\text{M}$  methionine were mixed in the presence of 5 mM phosphate buffer at pH 7. Then  $\text{ClO}_2^-$ ,  $\text{Cl}^-$ , and MSO were monitored over time. To achieve comparable results, it was ensured that IC and LC were always measured simultaneously (same time of sample injection). The total period was set to 24 hours.  $\text{Cl}^-$  samples need to be blank corrected and the impurity of  $\text{ClO}_2^-$  solutions (purity = 80%) also contains  $\text{Cl}^-$ . Thus, the  $\text{Cl}^-$  concentration of the impurity needs to be determined as well and subtracted from the final result.

To investigate the follow-up reaction of methionine with benzoquinone, as reactive organic transformation product, 100  $\mu\text{M}$  methionine and 100  $\mu\text{M}$  benzoquinone were mixed at pH 7 and MSO formation was monitored for 18 hours.

## Results and discussion

### Reaction kinetics

To investigate if methionine is a suitable scavenger for the intrinsically formed FAC as the secondary oxidant in  $\text{ClO}_2$ -based reactions, two features are necessary. First, the second-order reaction rate constant for the reaction with FAC should be high, which has been reported for methionine to be  $k_{\text{app}} = 6.8 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$  at pH 7.<sup>14</sup> Furthermore, the second-order reaction rate constant for the reaction with  $\text{ClO}_2$  should be several orders of magnitude lower. The second-order rate constant for the reaction of methionine and  $\text{ClO}_2$  has not been reported in the literature yet. Table 1 shows the obtained pseudo-first-order reaction rate constants and the second-order reaction rate constants for different ratios between methionine and  $\text{ClO}_2$ .

Overall, the second-order rate constant of methionine with  $\text{ClO}_2$  is low ( $10^{-2} \text{ M}^{-1} \text{ s}^{-1}$ ) and ten orders of magnitude lower than the corresponding reaction with FAC. Thus, methionine can effectively and selectively scavenge FAC in the presence of  $\text{ClO}_2$ .

### Formation of chloride and MSO

It was investigated if  $\text{Cl}^-$  is the only inorganic reaction product of the reaction of methionine and FAC. In that, different concentrations of FAC were added to a 0.1 mM methionine solution and measured with IC. The relative yields based on the dosed FAC concentration are shown in Fig. 1. It is visible that  $\text{Cl}^-$  is the main reaction product in this reaction, with yields ranging between 90 and 110%. The

**Table 1** Results of pseudo-first order kinetic reactions of methionine with  $\text{ClO}_2$ . The reaction solution contained different concentrations of methionine (5 and 50 mM) and 5 mM phosphate buffer at pH 7. 0.5 mM  $\text{ClO}_2$  was dosed to all samples, and all experiments were carried out in triplicates

Molar ratios methionine : $\text{ClO}_2$	$k_{\text{obs}}$ [ $\text{s}^{-1}$ ]	$k_{\text{app}}$ [ $\text{M}^{-1} \text{s}^{-1}$ ]
1 : 10	$5.05 (\pm 0.02) \times 10^{-5}$	$1.01 (\pm 0.01) \times 10^{-2}$
1 : 100	$5.82 (\pm 0.02) \times 10^{-4}$	$1.16 (\pm 0.01) \times 10^{-2}$

standard deviation of the triplicate measurement is relatively high in this experiment, which can be explained by the high  $\text{Cl}^-$  background concentrations in the FAC stock solution. Despite the high  $\text{Cl}^-$  background concentrations, precise determination of  $\text{Cl}^-$  is possible. It has to be mentioned that no other chlorine species (*i.e.*,  $\text{ClO}_2^-$ , chlorate ( $\text{ClO}_3^-$ )) were detected in this experiment, indicating that the reaction of FAC with methionine forms 100%  $\text{Cl}^-$  which is according to the proposed reaction mechanism (Fig. S1†).<sup>14</sup>

The formation of MSO as the reaction product of the reaction of methionine with FAC has been investigated as well. Thereby, the focus was to determine the yield of MSO per FAC consumed. The MSO yields are later required to correlate with intrinsically formed FAC yields when methionine is applied as a FAC scavenger. For this purpose, FAC was added in different concentrations to methionine and the formed MSO was measured (determined using commercially available MSO standards). The amount of FAC added was then correlated with MSO formed to determine the MSO yield (Fig. 2).

The correlation of MSO formation with added FAC shows a linear trend. Based on the slope of the plot, which is very close to 1, it can be stated that the stoichiometry of the proposed reaction mechanism is 1, *i.e.*, one molecule of MSO is formed per molecule of FAC consumed.

### Chlorine mass balance of model compounds during reactions with chlorine dioxide

Phenol, hydroquinone, and DMP have been chosen as model compounds since their chlorine balance is known. While phenol is reported to form 50% FAC and 50%  $\text{ClO}_2^-$ ,<sup>4,5</sup> hydroquinone and DMP are reported to form 100% chlorite.<sup>6,8,9,21,22</sup> These data will later be compared to the chlorine balances measured with the methionine method.

The determined chlorine mass balance for phenol is shown in Fig. 3. Fig. 3A shows all species formed in this reaction ( $\text{Cl}^-$ ,  $\text{ClO}_2^-$ , and MSO). Additionally, direct addition of FAC to an aliquot of the reaction solution displays close to 100% turnover to MSO (recovery (REC)). This indicates that methionine is added in sufficient concentrations to effectively scavenge intrinsically formed FAC (if formed) and yield MSO.

As demonstrated before, FAC reacts with methionine in a 1 : 1 stoichiometric ratio and forms 1 mole of  $\text{Cl}^-$  and MSO. Therefore, if MSO and  $\text{Cl}^-$  are included in the mass balance, the total yield would be >100%. For instance, if a compound forms 50% FAC and 50%  $\text{ClO}_2^-$  in the reaction with  $\text{ClO}_2$ , FAC would react with methionine and form 50%  $\text{Cl}^-$  and 50% MSO (relative to the dosed molar  $\text{ClO}_2$  concentration). Hence, the  $\text{Cl}^-$  and MSO yields need to be converted into FAC yields. Thereby it has to be considered that  $\text{Cl}^-$  and MSO can form from reactions not involving FAC, while equal yields of  $\text{Cl}^-$  and MSO are formed in the reaction of FAC with methionine.

**Fig. 1** Relative yields of chloride based on the dosed concentration of FAC. Solutions contained 1 mM methionine and 5 mM phosphate buffer at pH = 7. All experiments were carried out in triplicates and the linear regression is based on all data points of the triplicate measurement.

**Fig. 2** Correlation of MSO formation with the addition of FAC. Reaction solutions contained 1 mM methionine and 5 mM phosphate buffer at pH 7. All experiments were carried out in triplicates, and the linear regression is based on all data points of the triplicate measurement.

**Fig. 3** Measured relative chlorine and MSO yields from the reaction of  $\text{ClO}_2$  with phenol in presence of methionine. The yields are based on the dosed  $\text{ClO}_2$  concentration. (A) shows the yields of all compounds (please note that chloride is formed in the reaction of FAC with methionine), (B) shows the remaining MSO fraction after subtracting the chloride yields from MSO yields (remaining MSO is labeled as MSO from unknown source). All reaction solutions contained 0.1 mM phenol, 1 mM methionine, and 5 mM phosphate buffer at pH = 7. All experiments were carried out in triplicates, and the error bars represent the standard deviation of the triplicate measurement; REC: recovery rate of FAC after addition of FAC to an aliquot of the reaction solution containing phenol and methionine.

Accordingly, formed FAC equals the yield of  $\text{Cl}^-$  if MSO is formed at higher concentrations than  $\text{Cl}^-$  and vice versa. (i.e.,  $[\text{FAC}] = [\text{MSO}]$ , if  $[\text{MSO}] \leq [\text{Cl}^-]$ ;  $[\text{FAC}] = [\text{Cl}^-]$  if  $[\text{MSO}] \geq [\text{Cl}^-]$ ). In this case, the formed  $\text{Cl}^-$  yields (gray columns in Fig. 3A) represents the formed FAC in this reaction, which is in accordance with previously reported literature values for phenol (40–50%).<sup>4,5</sup> After subtracting  $\text{Cl}^-$  yields from MSO yields, a fraction of MSO remains, labeled as unknown in

Fig. 3B, which is not formed from the reaction of FAC with methionine. Thus, MSO must be formed during a different reaction pathway involving different reaction partners. This could point to a reaction of  $\text{ClO}_2^-$  with methionine. However, in this experiment,  $\text{ClO}_2^-$  is formed with a 50% yield of the dosed  $\text{ClO}_2$  concentration, which is in accordance with the previously reported literature.<sup>4,5</sup> Therefore, MSO might be formed by reactive organic species, which are formed during

**Fig. 4** Measured relative chlorine and MSO yields from the reaction of  $\text{ClO}_2$  with hydroquinone (A) and DMP (B) in presence of methionine. The yields are based on the dosed molar  $\text{ClO}_2$  concentration. All reactions contained 0.1 mM of either hydroquinone or DMP, 1 mM methionine, and 5 mM phosphate buffer at pH 7. All experiments were carried out in triplicates, and the error bars represent the standard deviation of the triplicate measurements; REC: recovery rate of FAC after addition of FAC to an aliquot of the reaction solution containing phenol and methionine.

the reaction of phenol with  $\text{ClO}_2$ . It is postulated that the reaction of  $\text{ClO}_2$  with phenol forms benzoquinone,<sup>21</sup> a weak oxidant with a standard reduction potential of 0.6992 V,<sup>23</sup> which might be reactive toward methionine. Another explanation could be the formation of reactive intermediates (*i.e.*, phenoxy radicals),<sup>24</sup> which could also react with methionine. The reaction of these reactive products or intermediates with methionine would also explain the lower  $\text{Cl}^-$  yields compared to MSO.

The chlorine balances of two other compounds have been investigated as well. Hydroquinone is also a phenolic moiety with a second hydroxyl group in the *para*-position. Hydroquinone is reported to form 100%  $\text{ClO}_2^-$ .<sup>6,8,21</sup> DMP is also reported to form 100%  $\text{ClO}_2^-$ ;<sup>9</sup> however, the reactive moiety of DMP is a tertiary amine. This compound is investigated as well to discover if different functional groups have different outcomes in the chlorine balances. Fig. 4 shows the chlorine balances of hydroquinone (A) and DMP (B).

In both cases, the main inorganic product is  $\text{ClO}_2^-$ , which is in accordance with the literature. However, the yields of  $\text{ClO}_2^-$  are below 100%. Additionally, the recoveries of MSO by dosing 100  $\mu\text{M}$  FAC directly into aliquots of either reaction solution without  $\text{ClO}_2$  ranges between 80–90%, which is lower compared to the results of phenol. An increase in the methionine concentration might support better results; however, due to the low solubility of methionine, the initial concentration could not be increased much further.

Based on literature data, no FAC should be formed in the reaction of hydroquinone and DMP with  $\text{ClO}_2$ . However, in this experiment, 20–30% MSO is detected. The simultaneously formed  $\text{Cl}^-$  concentrations are much lower, which indicates, that not FAC but another reactive organic species is formed during the reaction. The hypothesized reactive species may cause the oxidation of methionine to MSO similar to phenol (*e.g.*, benzoquinone, semiquinone, or phenoxy radical in case of hydroquinone, cation radical in case of DMP).

Another critical aspect is the overall chlorine recovery. The sum of  $\text{Cl}^-$  and  $\text{ClO}_2^-$  is around 80% which is lower than the dosed  $\text{ClO}_2$  concentration. A loss in the chlorine mass balance typically indicates the formation of halogenated products. However, from the reaction of DMP and hydroquinone with  $\text{ClO}_2$ , no halogenated reaction products are reported.<sup>12</sup> It might be possible that the presence of methionine interferes with the reaction pathway and causes the chlorination of organic compounds. For both compounds, the overall chlorine mass balance shows an increasing trend with increasing  $\text{ClO}_2$  dose, mainly due to the increasing yields of  $\text{ClO}_2^-$ . This might be caused by the fact that the effect of side reactions is reduced with a higher degree of reactant oxidation by  $\text{ClO}_2$ . Further experiments are necessary to investigate if this effect is canceled out completely at one point, where the  $[\text{ClO}_2^-]/[\text{reactant}]$  fold increased.

To investigate if the developed method can be applied to study sulfur-containing compounds, GSH has been chosen as

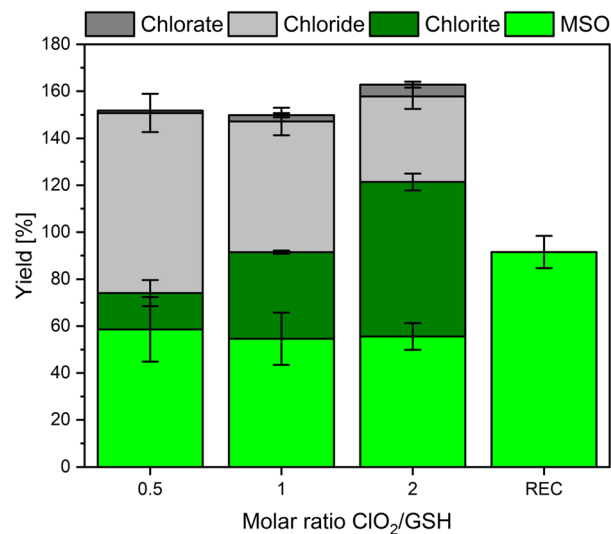

Fig. 5 Chlorine balance of GSH established by using the methionine method. A reaction solution containing 0.1 mM GSH, 5 mM phosphate buffer, and 1 mM methionine at pH 7 were mixed with different concentrations of  $\text{ClO}_2$ . All experiments were carried out in triplicates, and the error bars represent the standard deviation.

a model compound. The determined chlorine mass balance and the FAC recovery are shown in Fig. 5. Please note that minor yields (<5%) of  $\text{ClO}_3^-$  were detected as well (dark gray columns Fig. 5). The low formation of highly oxidized form of chlorine might be caused by side reactions of *e.g.*,  $\text{ClO}_2$  with FAC.<sup>12</sup> The FAC recovery (REC), measured as formed MSO, is nearly complete (92%). Thus, if FAC is formed in this reaction, it will be scavenged by methionine. For GSH, the yields of inorganic chlorine species show a strong dependency on the  $\text{ClO}_2$  dose. If  $\text{ClO}_2$  is dosed in a molar ratio of 0.5 : 1 to GSH, the most dominant reaction product is  $\text{Cl}^-$ . The higher the stoichiometric ratio, the more dominant  $\text{ClO}_2^-$  becomes. This might be explainable by follow-up reactions of  $\text{ClO}_2^-$  with residual GSH concentration. The reaction of  $\text{ClO}_2^-$  with GSH is very slowly and forms  $\text{Cl}^-$  (see Fig. S2†). The stoichiometry of this reaction has been determined to be two moles of GSH reacting with one mole of  $\text{ClO}_2^-$  (see Fig. S4†), which is in accordance with reported literature values.<sup>18</sup> Please note that the  $\text{Cl}^-$  yields were determined by experiments where  $\text{ClO}_2^-$  was in two to five-fold excess over GSH. However, further experiments are necessary to determine if the chlorine balance changes significantly if GSH is present in excess over  $\text{ClO}_2^-$  (*i.e.*, shift in the molar yields of  $\text{Cl}^-$ ). The principle of the reaction of GSH and  $\text{ClO}_2$  for the dosed  $\text{ClO}_2$  concentrations is shown in Fig. 6.

In case 50  $\mu\text{M}$   $\text{ClO}_2$  is dosed to 100  $\mu\text{M}$  GSH (Fig. 6A),  $\text{ClO}_2$  will be fully consumed, and 50% of  $\text{ClO}_2$  will be transformed to FAC (25  $\mu\text{M}$ ), and 50% will be transformed to  $\text{ClO}_2^-$  (25  $\mu\text{M}$ ), which leaves 75  $\mu\text{M}$  GSH (reaction stoichiometry of  $\text{ClO}_2:\text{GSH}$  2:1 see Text S1 and Fig. S3†). This quantity of GSH will react with  $\text{ClO}_2^-$  in a 2:1 stoichiometry (Fig. S4†), eventually forming 25  $\mu\text{M}$   $\text{Cl}^-$  and

**Fig. 6** Postulated reaction pattern of GSH in case of different dosed  $\text{ClO}_2$  concentrations at pH 7 in presence of 1 mM methionine. (A) Molar ratio GSH :  $\text{ClO}_2$  2 : 1; (B) molar ratio GSH :  $\text{ClO}_2$  1 : 1; (C) molar ratio GSH :  $\text{ClO}_2$  1 : 2.

leaving a fraction of 25  $\mu\text{M}$  GSH. In this case, in total, 50  $\mu\text{M}$   $\text{Cl}^-$ , 25  $\mu\text{M}$  MSO, and 0  $\mu\text{M}$   $\text{ClO}_2^-$  should be formed in the

final sample, which are 100, 50, and 0% of the dosed  $\text{ClO}_2$  concentration, respectively. This changes if the dosed  $\text{ClO}_2$

**Fig. 7** Proposed reaction mechanism for glutathione with chlorine dioxide. GSH reacts with two molecules of  $\text{ClO}_2$  and forms  $\text{ClO}_2^-$  and  $\text{HOCl}$ .

concentration is increased (Fig. 6B and C), whereby the fraction of GSH available for follow-up reaction with  $\text{ClO}_2^-$  is getting reduced. The theoretical values in Fig. 6 are in good accordance with the measured values in Fig. 5. The differences in yields of  $\text{ClO}_2^-$  can be explained by the different reaction times used to generate the data in Fig. 5 and S2.† Since the reaction of  $\text{ClO}_2^-$  with GSH is very slow, the reaction in Fig. 5 did not fully proceed. Based on the observed results, it can be concluded that FAC is formed in the reaction of  $\text{ClO}_2^-$  with GSH during a two-step reaction mechanism, which is shown in Fig. 7.

### MSO formation by follow-up reactions

Previous results indicated a slow but possible reactivity between methionine and some transformation products. To investigate this hypothesis,  $\text{ClO}_2^-$  and methionine were mixed with a molar ratio of 1 : 1, and the evolution of  $\text{ClO}_2^-$  and formation of MSO was monitored for 24 h (sampling rate: 1 sample per 40 min). The results are shown in Fig. 8.

It can be stated that  $\text{ClO}_2^-$  is not significantly degraded during the investigated time frame. In contrast, MSO is formed instantaneously by around 30% (of the initial molar methionine concentration) and shows a slightly decreasing trend during the investigated period.  $\text{Cl}^-$  was also monitored in this experiment. However, after subtracting the  $\text{Cl}^-$  concentration of the blank samples and the impurities of the  $\text{ClO}_2^-$  solution, the remaining value residual concentration for  $\text{Cl}^-$  was below zero. It has to be noted that the sensitivity of the  $\text{Cl}^-$  measurement is strongly affected due to the high  $\text{Cl}^-$  background concentration in the  $\text{ClO}_2^-$  solution. Based on these results, it can be stated that  $\text{ClO}_2^-$  does not react with methionine. However, MSO is formed from an unknown source. So far, it cannot be explained why MSO is formed in the presence of  $\text{ClO}_2^-$  and is not formed in the absence of  $\text{ClO}_2^-$ , although no  $\text{ClO}_2^-$  degradation can be observed. One possibility might be the presence of 20% impurities in  $\text{ClO}_2^-$  stock solutions. Although the impurities mainly consist of

$\text{Cl}^-$ , it might be possible that other impurities may be reactive towards methionine. Note that  $\text{ClO}_3^-$  and  $\text{OCl}^-$  were not detected in  $\text{ClO}_2^-$  standards. The slow degradation of MSO over time might be explainable by the formation of methionine sulfone. It is reported that sulfoxides might be further oxidized to sulfones.<sup>25</sup> However, the formation of methionine sulfone was not observed in this study.

The follow-up reaction of methionine with benzoquinone has been investigated as well. Therefore, benzoquinone and methionine were mixed in a 1 : 1 ratio and MSO formation was monitored over time (Fig. 9).

The results show that MSO also forms in the reaction of methionine and benzoquinone; however, only small yields of MSO have been formed after 18 h reaction time (4–5% per added benzoquinone). This shows that methionine can react with benzoquinone to form MSO but it does not explain the 30% MSO yields in case of hydroquinone or 1,4-DMP. This indicates that MSO formation from other reactants than FAC is a complex interplay of different intrinsically formed reactive species such as semiquinone or phenoxy radicals.

## Conclusion and outlook

Based on the results of this study, it can be concluded that methionine can scavenge intrinsically formed FAC in  $\text{ClO}_2^-$ -based reaction mechanisms and form a product which is not reactive. Thus, the scavenger is less prone in causing interferences compared to *e.g.*, glycine which forms  $\text{Cl-Gly}$ . However, further investigations are necessary to use this method for intrinsically formed FAC quantification. Even though the reaction of methionine and FAC leads to the formation of MSO and  $\text{Cl}^-$  in a 1 : 1 ratio, the additional formation of MSO from a yet unknown source (*i.e.*, potential reaction of reactive intermediates with methionine) might bias the final results. It seems that this unknown reaction with methionine does not form  $\text{Cl}^-$ . Therefore it is possible to quantify the MSO yields caused by the reaction with FAC. However, if the chlorine balance is not known many

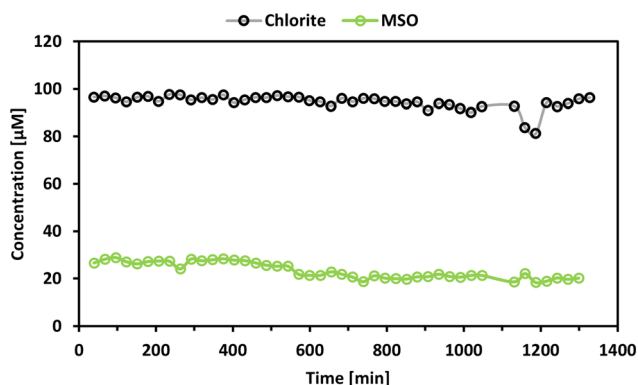

Fig. 8 Monitoring the reaction of  $\text{ClO}_2^-$  and methionine by  $\text{ClO}_2^-$  degradation and MSO formation for 24 hours. The reaction solution contained 0.1 mM methionine and 5 mM phosphate buffer at pH 7. 0.1 mM  $\text{ClO}_2^-$  was added and measured with IC and LC-MS/MS.

Fig. 9 Formation of MSO in the reaction of benzoquinone and methionine at pH 7. The solution contained 100 µM benzoquinone, 100 µM methionine, and 5 mM phosphate buffer at pH 7. The formation of MSO was monitored for approximately 18 hours.

assumptions have to be made, which makes quantification of FAC yields difficult. Especially, in the case of GSH, where a stoichiometry-dependent chlorine balance was observed, it is hard to predict exactly which fraction of MSO is formed by FAC. One possible option to solve this problem is combining this method with an existing method. It would be for example possible to quantify the  $\text{ClO}_2^-$  yields of the reaction of GSH with  $\text{ClO}_2$  in presence of glycine as FAC scavenger to avoid any interferences by FAC.<sup>17</sup> Then only the FAC yields are unknown and could be determined by using the methionine method, since MSO is more stable than Cl-Gly.<sup>8</sup> Additionally, it still needs to be investigated which other reactive species or generally which factors may contribute in to MSO formation. Even though the methionine method does not seem suitable for quantification of FAC yields, it can be used to make qualitative statements about FAC formation. For instance, GSH seems to form FAC, however, precise FAC yields are yet unclear and their determination requires further investigations.

## Safety precautions

Chemicals can be hazardous and have to be used with care. Especially  $\text{ClO}_2$  is toxic, volatile, and explosive. Hence, the production and application of  $\text{ClO}_2$  have to be done in a suitable fume hood. Measures have to be applied for disposing  $\text{ClO}_2$ -containing solutions after work. All precautions of the manufacturers regarding instruments and chemicals have to be studied and applied with care. All general laboratory safety rules have to be applied carefully.

## Conflicts of interest

There are no conflicts of interest to declare.
