Aminotriazine derived N-doped mesoporous carbon with a tunable nitrogen content and their improved oxygen reduction reaction performance†

Jefferin M. Davidraj,^a C. I. Sathish,^{ib} ^{*,a} Premkumar Selvarajan,^b Mohammed Fawaz,^a Vibin Perumalsamy,^a Xiaojiang Yu,^c Mark B. H. Breese,^c Jiabao Yi^{*,a} and Ajayan Vinu^{ib} ^{*,a}

The electrocatalytic activity of carbon materials is highly dependent on the controlled modulation of their composition and porosity. Herein, mesoporous N-doped carbon with different amounts of nitrogen was synthesized through a unique strategy of using a high nitrogen containing CN precursor, 3-amino 1,2,4 triazine (3-ATZ) which is generally used for the preparation of carbon nitrides, integrated with the combination of a templating method and high temperature treatment. The nitrogen content and the graphitisation of the prepared materials were finely tuned with the simple adjustment of the carbonisation temperature (800–1100 °C). The optimised sample as an electrocatalyst for oxygen reduction reaction (ORR) exhibited an onset potential of 0.87 V vs. RHE with a current density of 5.1 mA cm⁻² and a high kinetic current density (J_k) of 33.1 mA cm⁻² at 0.55 V vs. RHE. The characterisation results of the prepared materials indicated that pyridinic and graphitic nitrogen in the carbon framework promoted ORR activity with improved four-electron selectivity and excellent methanol tolerance and stability. DFT calculations demonstrated that the structural and planar defects in the N-doped carbon regulated the surface electronic properties of the electrocatalyst, leading to a reduction in the energy barrier for the ORR activity. This strategy has the potential to unlock a platform for designing a series of catalysts for electrochemical applications.

1. Introduction

The surge in the development of renewable energy storage and conversion technologies is driven by the urgent need to address the environmental crisis caused by over-reliance on fossil fuel-based energy generation. With ongoing developments, proton exchange membrane fuel cells (PEMFC) emerge as promising green energy alternatives because of their impressive efficiency in converting different fuels into electric energy, offering a clean and sustainable way to mitigate the global energy crisis. However, there are still limiting factors

that put hurdle in the path of their performance and commercialisation, including the sluggish nature of the ORR.^{1–7} To overcome these limitations, many noble metal-based nanoparticles (Pt, Ir and Ru) and their alloys have been widely used as catalysts for ORR. However, CO poisoning, limited stability, scarcity, and the high cost of noble metals restrict their wide industrial applications. Owing to these reasons, there has been significant interest recently in developing highly efficient and low-cost electrocatalysts for ORR.⁸ In recent years, heteroatom-doped carbon materials have been broadly studied,^{2,9–13} but those containing nitrogen substitutions, particularly, have gained significant attention as ORR catalysts owing to their excellent electron transfer kinetics, long-term stability, scalability and low cost.^{4,8,14–17} Among them, graphitic carbon nitride (g-C₃N₄) with a high nitrogen content is a promising candidate for boosting the ORR activity as the N functionalities in g-C₃N₄ can induce a more positive charge density on adjacent carbon atoms due to their different atomic sizes and higher electronegativity than carbon.^{2,15} This effect is beneficial for weakening the O–O bond, promoting oxygen molecule chemisorption and the overall ORR catalytic process.^{17–19}

However, the lack of electronic conductivity and the poor specific surface area of g-C₃N₄ are the major drawbacks which limit its performance in the ORR, highlighting an area for further exploration.^{20–24}

Previous studies focused on introducing micropores and mesopores into the carbon nitride structure with a high nitrogen content to improve its specific surface area and pore volume, contributing to enhanced active sites and ion transport.^{25–28} Although a family of high nitrogen-containing mesoporous carbon nitrides (MCNs) like C₃N₅, C₃N₆ and C₃N₇ with unique chemical structures and a high specific surface area has been successfully prepared by varying the nature of the carbon nitride precursors,^{2,25,26,29–31} the poor conductivity of these materials is the major issue as it significantly affects the efficiency of the catalysts in the ORR. Therefore, developing high-performance ORR catalysts with a high number of active sites and high electronic conductivity for ORR remains a topic of interest. It is surmised that catalysts with the properties of both CN and graphitic carbon can offer high conductivity but at the same time change the local density state of bonded carbon atoms with nitrogen to increase the charge density on the adjacent carbon atoms. This simple manipulation is believed to be a key factor in enhancing the ORR performance as it may increase the number of active sites and Lewis basic sites.^{2,32,33}

In this work, we developed a mesoporous nitrogen-doped porous carbon through a hard templating approach using SBA-15 and 3-amino 1,2,4 triazine (3-ATZ) as a dual carbon and nitrogen precursor, which is generally used for the preparation of carbon nitride materials, by treating at different high carbonization temperatures. The prepared materials exhibit a mesoporous structure with structural and planar defects favouring the formation of pyridinic, pyrrolic and graphitic N at the edge sites which contribute more π electrons to the π system. The prepared catalyst displayed a high specific surface area of 759.6 m² g^{−1} and a high pore volume of 1.61 cm³ g^{−1}. The nitrogen content in the mesoporous carbon can be tuned with the simple adjustment of the carbonisation temperature which in turn controls the number of active sites and the conductivity of the materials. The optimised N-doped and ordered mesoporous carbon sample treated at high carbonisation temperature showed superior electrocatalytic performance for ORR with a half-wave potential ($E_{1/2}$) of 0.78 V, excellent stability and resistance towards methanol. With the help of DFT calculations, we predicted that the pyridinic and pyrrolic N contents at the edge sites, formed after treating at high carbonisation temperature, are crucial in promoting and enhancing the ORR activity in ordered mesoporous N-doped carbon.

2. Experimental method

2.1. Synthesis of mesoporous N-doped carbon from 3-ATZ using SBA-15 as a template

Mesoporous N-doped carbons were synthesized using SBA-15 as a sacrificial template and 3-ATZ as a C and N precursor.³⁴ Initially, the SBA-15 template was prepared using pluronic

P123 surfactant *via* a soft templating method at 150 °C through a procedure described in the earlier reports.^{34–37} For the preparation of mesoporous N-doped carbon, 1 g of the SBA-15 template was mixed and ground thoroughly with 4 g of 3-ATZ using a mortar and pestle. A solution containing 0.64 g of concentrated HCl in 5 ml water was added to the ground mixture. This solution helps in filling the pores of the silica template with 3-ATZ using a pore-filling method. The resulting sample was then placed in a hot-air oven and heated at 100 °C for 6 h, followed by heating at 160 °C for another 6 h. After the above steps, the composite was carbonized at various temperatures (800, 900, 1000, and 1100 °C) with a heating rate of 5 °C min^{−1} for 5 h. The carbonization process was carried out in a tubular furnace under a nitrogen atmosphere. Once the carbonization was completed, the silica template was removed by washing with hydrofluoric acid (HF), and then the sample was extensively washed with ethanol to eliminate any remaining HF. The samples were then dried in a 100 °C oven for overnight and the final product was labelled as NMC-AT-800, NMC-AT-900, NMC-AT-1000 and NMC-AT-1100 based on the carbonization temperature at 800, 900, 1000, and 1100 °C respectively. The high carbonisation temperature was used to improve the crystallinity and further to tune the N content in the graphitic carbon framework of NMC-AT materials. The color of the final NMC-AT materials was black.

2.2. Characterization

The structure of NMC-AT samples was studied using a powder X-ray diffractometer Empyrean from PANalytical instruments. The sample was ground into fine powder and loaded into the sample holder and irradiated using Cu-K α radiation (λ = 1.5405 Å) which operates at a voltage and current of 40 kV and 40 mA, respectively. XRD patterns were collected in the region 2θ = 10°–80° using a step size of 0.007. The d -spacing was calculated using the Braggs law $\lambda = 2d \sin(\theta)$, where λ is the wavelength of the X-ray beam, d is the distance and θ is the diffraction angle. N₂ adsorption–desorption isotherms were obtained at liquid nitrogen temperature (−196 °C) using a Micromeritics ASAP 2420 analyser. All the samples were degassed at 200 °C for 12 h prior to the measurements. The surface area was obtained using the Brunauer–Emmett–Teller (BET) method. The total pore volume was taken from the adsorption point at a relative pressure (P/P_0) of 0.99. The surface morphology of the sample was investigated using scanning electron microscopy (SEM) from JEOL with the model JSM-7900F. FTIR analysis was performed using a Frontier MIR/NIR spectrometer (PerkinElmer) using the standard KBr method. Raman spectra were recorded on a Renishaw confocal spectrometer with 633 nm laser excitation. X-ray photoelectron spectroscopy (XPS) analysis was carried out using the multiprobe photoelectron spectrometer from Omicron Nanotechnology. Peak fitting and atomic concentrations were carried out using the CasaXPS software. Near-edge X-ray absorption fine structure (NEXAFS) was obtained on the Soft X-ray Spectroscopy Beamline at the Singapore synchrotron facility in Singapore.

2.3. Electrochemical ORR measurement

Electrochemical ORR studies were carried out in a three-electrode system at room temperature using a Pine electrochemical workstation coupled with a galvanostat/potentiostat. A glassy carbon electrode (GCE) of 5 mm diameter was used as a working electrode, which was well-cleaned before electrochemical experiments. The sample ink was prepared in a 2 ml vial, where 5 mg of the sample, 50 μL of 5 wt% Nafion solution and 950 μL isopropyl alcohol were sonicated for an hour to obtain a well-homogenized suspension. About 10 μL of the suspension was added dropwise onto the GCE and dried at room temperature. In a basic O_2 -saturated aqueous 0.1 M KOH electrolyte environment, a platinum wire was immersed as the counter electrode and Ag/AgCl as the reference electrode, and RDE measurements were carried out. The number of electrons transferred per oxygen molecule was calculated using the Koutecky–Levich equation as given below:

$$\frac{1}{j} = \frac{1}{j_k} + \frac{1}{j_d} = \frac{1}{j_k} + \frac{1}{0.62 n F (D_{\text{O}_2})^{2/3} \nu^{-1/6} C_{\text{O}_2} \omega^{1/2}}$$

where, j is the measured current density; j_k and j_d are the kinetic and diffusion-limited current density, respectively; n is the overall electron number transferred per oxygen molecule during the ORR; F represents the Faraday constant (96 485 C mol^{-1}); D_{O_2} is the diffusion coefficient of O_2 in the electrolyte ($1.9 \times 10^{-5} \text{ cm}^2 \text{ s}^{-1}$ in 0.1 M KOH); ν is the kinematic viscosity of the electrolyte ($0.01 \text{ cm}^2 \text{ s}^{-1}$); C_{O_2} is the bulk concentration of O_2 in the electrolyte ($1.2 \times 10^{-6} \text{ mol cm}^{-3}$ in 0.1 M KOH); ω is the rotating rate of the electrode (rad s^{-1}).

2.4. Computational methods

All the first-principles calculations were performed with the Vienna *ab initio* Simulation Package (VASP) based on density functional theory.^{38,39} The projector augmented wave (PAW) method was considered for core electrons, and the Perdew–Burke–Ernzerhof (PBE) exchange–correlation functional was used to represent valence electrons.⁴⁰ For all the calculations, an energy cutoff of 520 eV was used. A vacuum space of 20 Å along the z direction was considered for all calculations to avoid interactions between the different nearest neighbouring layers. Bader charge analysis was carried out to understand the charge-transfer interactions.⁴¹

The adsorption energy was calculated using the formula,

$$E_{\text{Ads}} = E_{\text{NMC-AT}+\text{O}_2} - (E_{\text{NMC-AT}} + E_{\text{O}_2})$$

where, E_{Ads} is the adsorption energy between NMC-AT and O_2 molecules. $E_{\text{NMC-AT}+\text{O}_2}$ is the total energy of O_2 adsorbed NMC-AT. $E_{\text{NMC-AT}}$ and E_{O_2} are the energy of the NMC-AT and O_2 , respectively.

3. Results and discussion

The synthesis of NMC-AT samples is schematically represented in Fig. 1. From the key synthesis steps schematized, the con-

finement of 3-amino 1,2,4-triazine into the sacrificial mould of SBA-15 restricted the movement of the precursor molecules, and the thermal treatment promoted the formation of interconnected carbon and nitrogen pore networks. Powder X-ray diffraction was used to investigate the crystal structure of the NMC-AT samples prepared at different carbonisation temperatures. As shown in Fig. 2a, all the samples showed broad diffraction peaks at the 2θ angle of ~ 25.8 to 26.07° and $\sim 44.3^\circ$ corresponding to the (002) and (101) plane of graphitic carbon. The two tiny peaks at 17.1 and 55.3° in NMC-AT-1100 correspond to the impurities at the time of measurement.

The XRD pattern of these samples showed a small shift of the (002) peak towards a lower angle as the carbonisation temperature increased from 800 to 1100 $^\circ\text{C}$. The corresponding interlayer distance calculated from the XRD patterns of the NMC-AT samples increased with increasing the carbonisation temperature, *i.e.* 0.341 nm (NMC-AT-800), 0.342 nm (NMC-AT-900), 0.344 nm (NMC-AT-1000), and 0.345 nm (NMC-AT-1100), respectively. This shift could be due to the fact that the high carbonisation temperature helps to improve the polymerization and condensation reaction of the 3-ATZ precursor within the nanochannels of the template which leads to improved graphitization of the carbon structure inside the pores of the final samples. The combined effect of the thermal expansion and potential changes in the carbon structure at high temperatures could have led to a higher d -spacing value.⁴² Noticeably, the samples did not show any lower angle peaks, indicating the absence of a long-range periodic arrangement of the mesoporous structure.⁴³

N_2 adsorption–desorption analysis was carried out to understand the surface properties of the NMC-AT samples. The isotherms of NMC-AT samples shown in Fig. 2b display a type IVa isotherm with an H3 hysteresis loop of the IUPAC classification. The feature of broad capillary condensation noticed at the higher relative pressure regions indicates that NMC-AT samples contained a mesoporous structure with disordered pores and broad pore size distribution. The textural properties of the NMC-AT samples are summarized in Table 1. The sample NMC-AT-900 displayed the highest specific surface area of $759.6 \text{ m}^2 \text{ g}^{-1}$ among all the samples, while NMC-AT-800 exhibited a surface area of $634.1 \text{ m}^2 \text{ g}^{-1}$. When the calcination temperature increased above 900 $^\circ\text{C}$, a significant reduction in the specific surface area was observed. The specific surface area was reduced from 682.9 and $589.4 \text{ m}^2 \text{ g}^{-1}$ when the carbonization temperature was increased from 1000 to 1100 $^\circ\text{C}$. The reduction in the specific surface area for NMC-AT-1000 and NMC-AT-1100 could be due to the defects and collapsed structure in the carbon framework that create large pores, adversely affecting the adsorption capacity of the samples. The pore size distribution analysis using the Barrett–Joyner–Halenda (BJH) method indicates that NMC-AT samples have mesopores with a moderate pore size of ~ 3.68 to 3.83 nm (Fig. S1†). Among the samples studied, NMC-AT-1000 exhibited the highest specific pore volume ($1.61 \text{ cm}^3 \text{ g}^{-1}$) and micropore surface area ($90.3 \text{ m}^2 \text{ g}^{-1}$). However, the micropore area ($50.2 \text{ m}^2 \text{ g}^{-1}$) and the pore volume ($1.24 \text{ cm}^3 \text{ g}^{-1}$) reduced

Fig. 1 Schematic representation of the synthesis of NMC-AT samples.

quite significantly when the carbonization temperature was raised to 1100 °C. The change in the specific surface area and the pore volume could be linked to a change in the microporosity and the final crystallinity of the materials at different carbonisation temperatures.

The surface morphology and the mesoporous structure of the NMC-AT samples were analyzed using SEM and TEM. As shown in Fig. S2,† all the NMC-AT samples displayed a porous structure. At the annealing temperature of 800 and 900 °C, a rod-like morphology was observed (Fig. S2a–d†). When the temperature increased to 1000 and 1100 °C, the morphology was changed from rod to sheet-like structures (Fig. S2e–h†). On the other hand, TEM analysis indicates that all the samples exhibited a sheet-like structure in high resolution, as shown in Fig. 2c, d and Fig. S3.† This change in morphology rather than a mesoporous ordered structure could be due to the collapse of the mesoporous channels and the temperature-assisted graphitization of carbon at elevated temperatures. The inset in Fig. 2d clearly shows both meso and micropores in the sample, as shown by the arrow, which may be due to the evaporation of nitrogen or carbon elements induced pores.

Raman spectroscopy analysis was carried out on the NMC-AT samples to identify the structural defects and N doping. As shown in Fig. 3a, Raman spectra showed two distinct peaks at around 1340 and 1570 cm⁻¹, corresponding to the D and G bands, respectively. The D band is associated with the disorder-induced structural defects on the graphitic plane, while the G band relates to the E_{2g} vibration mode present in the sp² carbon domains.^{44–46} The D and G bands of NMC-AT-1100 displayed a shift in the peaks to 1357 and 1583 cm⁻¹, respectively. The peak intensity ratio I_D/I_G indicates the amount of structural defects in the material and exposure of the edge plane. From the intensity ratio calculated, the NMC-AT-800 sample showed the highest I_D/I_G ratio of 1.08 and decreased further in NMC-AT-900 (1.06), NMC-AT-1000 (1.05), and NMC-AT-1100 (0.98). The incorporation of more nitrogen atoms into the graphite layers created structural defects and exposed the edge planes, resulting in high I_D/I_G ratios in NMC-AT-800. Likewise, the decrease in I_D/I_G ratios to 0.98 in NMC-AT-1100 indicates that the sp² domains are partially restored, and the graphitic degree is improved.

The elemental composition of NMC-AT samples was measured using a CHN analyser, and the corresponding

Fig. 2 (a) Powder X-ray diffraction patterns and (b) nitrogen adsorption–desorption isotherms of NMC-AT samples. (c) SEM image and (d) TEM image of the NMC-AT-1000 sample.

Table 1 Summary of the textural properties analysed through N_2 adsorption–desorption and the C and N ratio from CHN and XPS analysis of NMC-AT samples

Sample name	S_{BET} ($\text{m}^2 \text{g}^{-1}$)	Total pore volume ($\text{cm}^3 \text{g}^{-1}$)	t -Plot micropore area ($\text{m}^2 \text{g}^{-1}$)	Micropore volume ($\text{cm}^3 \text{g}^{-1}$)	Pore diameter (nm)	CHNS (at%) C/H/N	XPS (at%) C/N/O
NMC-AT-800	634.1	1.40	46.4	0.023	3.68	5.4/1.9/2.36	67.4/30.3/2.3
NMC-AT-900	759.6	1.51	43.9	0.026	3.70	6.59/1.4/1.38	81.1/17.5/1.4
NMC-AT-1000	682.9	1.61	90.3	0.039	3.83	7.14/1.14/0.92	85.9/12.3/1.8
NMC-AT-1100	589.4	1.24	50.2	0.024	3.73	7.76/0.74/0.42	92.4/5.7/1.9

results are summarized in Table 1. The increase in carbon and the decrease in nitrogen content directly correlate with the increase in heat-treatment temperature wherein the nitrogen is partially volatilized through gradual heating. The sample NMC-AT-800 displayed a high nitrogen content of 30.3 wt%, which should be defined as one kind of carbon nitride due to the high concentration of N. With the increasing heating temperature, the concentration of nitrogen gradually reduced to 5.7 wt% in NMC-AT-1100, signalling the formation of NMC-AT. This result is in good agreement with the Raman I_D/I_G ratios, indicating that the nitrogen content can be fine-tuned to create defects and expose edge planes for catalytic applications through a simple heat treatment process.

The chemical structure and the functional groups of NMC-AT were determined using FTIR spectroscopy. The FTIR spectra of NMC-AT samples are shown in Fig. 3b. The broad-band noticed from 2800 to 3600 cm^{-1} corresponds to the symmetric and antisymmetric stretching vibrations of primary and secondary amines. The peak at 1150, 1247 and 1532 cm^{-1}

corresponds to the sp^2 C–N stretching vibrations of the heterocyclics, and the peak at 737 cm^{-1} corresponds to the aromatic C–C.^{25,45} As can be seen from the figure, the peak at 1247 cm^{-1} related to the C–N binding and the intensity of the band gradually decrease with increasing carbonization temperature, which confirms the decrease in N moieties at high temperatures. The intense shoulder peaks at 977 and 1532 cm^{-1} confirm the pyridinic N nature in the graphene lattice.⁴⁷ The carbon and nitrogen bonding configuration and the elemental composition of NMC-AT samples were further investigated by X-ray photoelectron spectroscopy (XPS). As shown in Fig. S4,† the survey scan spectra of NMC-AT samples exhibited peaks corresponding to the C 1s, N 1s, and O 1s. From the spectra, we can notice that the N 1s peak intensity diminishes as the carbonization temperature increases and the O 1s spectra should have arisen due to the oxidation of the surface at high temperature. The XPS elemental analysis results are also summarized in Table 1, where the NMC-AT-800 sample shows the highest nitrogen content (30.3 At%) and is

Fig. 3 (a) Raman spectra and (b) FTIR of NMC-AT samples. (c) C 1s spectra and (d) N 1s spectra of NMC-AT-1000. (e) C K-edge and (f) N K-edge spectra of NMC-AT samples.

consistent with the CHN analysis. The results indicate that at a relatively low heating temperature, the sample may form carbon nitride. When the carbonisation temperature was increased, the transformation of carbon nitride to N-doped mesoporous carbon samples occurred.

The high-resolution C 1s spectra of NMC-AT samples, as shown in Fig. 3c and S5a–c,† are deconvoluted to three different peaks which are centred approximately at 284.4, 285.6, and 287.9 eV, respectively. The main peak in the C 1s spectra at 284.4 eV is assigned to the graphitic sp^2 carbon, and the peaks at 285.6 and 287.9 eV are ascribed to nitrogen bonded to sp^2 -C and sp^3 -C, respectively. The peak at 284.4 eV shifts to high binding energy in NMC-AT-800 (284.8 eV) but the peak is shifted to lower binding energy for NMC-AT-900 (284.4 eV), NMC-AT-1000 (284.32 eV) and NMC-AT-1100 (284.28 eV) as the carbonisation temperature is increased. A detailed summary of XPS deconvolutions is given in Table S1.† From the table, it can be observed that the peak area of C=C increases (41.03 to 71.68%), and a gradual decrease of C–N (50.06 to 18.84%) peak area in NMC-AT-800 to NMC-AT-1100 is noticed. This indicates that the carbon atoms partially replaced the nitrogen atoms in the graphitic domains as the carbonisation temperature is increased. Likewise, the high-resolution N 1s spectra (Fig. 3d and S5d–f)† are deconvoluted to three different peaks at 398.2, 400.4, and 402.7 eV. The peak positioned at 398.2 eV is assigned to the pyridinic nitrogen, which is heterogeneously bonded to two adjacent carbon atoms, whereas the peak at 400.4 eV is assigned to the pyrrolic-nitrogen, while the peak at 402.7 eV is assigned to the graphitic nitrogen.^{47,48} The N 1s spectra and Table S1† indicate a

decrease in the pyridinic-N peak ratio and a simultaneous increase in pyrrolic-N from NMC-AT-800 to NMC-AT-1100 samples, suggesting a shift in the nitrogen bonding environment within the material. The peak intensity ratio I_D/I_G from Raman analysis also supports this observation, further confirming that pyridinic nitrogen causes structural defects and exposed planar defects.⁴⁹ Moreover, from the XPS deconvolutions, it can be observed that the peak intensity attributed to the graphitic N significantly increases to a high value of 31.19% in NMC-AT-1100, suggesting that with the increase in carbonisation temperature, the graphitic N content in the graphite layers increases quite significantly.

Near-edge X-ray absorption fine spectroscopy (NEXAFS) was conducted to understand the electronic structure and the chemical bonding environment in the NMC-AT samples. Fig. 3e displays the C K-edge spectra of the NMC-AT samples which show four peaks at 285.2 (C1), 286.6 (C2), 288.3 (C3) and 292.6 eV (C4), respectively. The C1 and C4 peaks are assigned to the electron transition from 1s to π^* C=C and σ^* C–C transition states in graphitic structures, respectively. The C2 peak is assigned to the sp^2 hybridized carbon with nitrogen heterocycles C=N/C–N, whereas the C3 peak is attributed to π^* C–N–C or oxygen-containing functional groups of π^* C=O.^{25,46} Interestingly, we can note that the C2 peak in NMC-AT-800 is gradually suppressed with the concomitant increase in the intensity of the C1 peak as the carbonisation temperature is increased. The N K-edge spectra show four different peaks N1–N4, as shown in Fig. 3f. The peaks N1 and N2 at 398.3 and 399.4 eV are attributed to the π^* C–N–C excitation and the C=N–C, respectively. The N3 peak at 401.4 eV is

assigned to the π^* N-3C excitation, whereas N4 at 407.1 eV is ascribed to the π^* transition similar to pyridine.⁴⁵ It is evident from the N K-edge spectra that the peak intensity of N1 and N2 peaks in NMC-AT-800 gradually decreases with the increased annealing temperature, indicating the depletion of nitrogen. These results are consistent with FTIR, Raman, CHNS and XPS observations, which suggest that the amounts of nitrogen bonding configurations differ by varying the temperature, indicating the effective tuning of the nitrogen content in carbon using the technique in this work.

The electrochemical ORR activity of NMC-AT materials was investigated in 0.1 M KOH solution saturated with O₂. A linear sweep voltammetry (LSV) measurement with a rotating disk electrode (RDE) was employed to isolate and study the fundamental electrochemical process happening at the electrode interface. The LSV curves for the NMC-AT and Pt/C samples were analyzed at a scanning rate of 5 & 10 mV s⁻¹ and a rotating speed of 1600 rpm as shown in Fig. S6† and Fig. 4a. Noticeably, the sample NMC-AT-1000 displays a high activity towards the ORR in an alkaline electrolyte with an onset potential (E_{onset}) of 0.87 V (vs. RHE), a half-wave potential ($E_{1/2}$) of 0.78 V (vs. RHE) and a current density (J_L) of 5.1 mAcm⁻². Other samples exhibit E_{onset} , $E_{1/2}$ and J_L in the decreasing order of the NMC-AT-900 (E_{onset} = 0.83 V vs. RHE, $E_{1/2}$ = 0.73 V and J_L = 4.61 mAcm⁻²), NMC-AT-1100 (E_{onset} = 0.82 V vs. RHE, $E_{1/2}$ = 0.72 V and J_L = 4.08 mAcm⁻²), and NMC-AT-800 (0.78 V vs. RHE, $E_{1/2}$ = 0.67 V and J_L = 4.56 mAcm⁻²), respectively. The higher specific surface area (682.9 m² g⁻¹) and higher pore volume (1.61 cm³ g⁻¹) of NMC-AT-1000 compared to other samples influence the limiting current density. In addition, the presence of higher pyridinic and graphitic N in

NMC-AT-1000 helps to achieve the highest onset potential. Interestingly, the sample NMC-AT-800, with a high amount of nitrogen, displays a 50 mV negative shift in the onset potential and 100 mV in the half-wave potential. Likewise, the NMC-AT-1100 sample shows a better E_{onset} , $E_{1/2}$, but the decline noticed in the reduction current may be due to the high amount of graphitic N and low pyridinic and pyrrolic N compared to other samples.⁵⁰ The ORR results demonstrate that tailoring the nitrogen content and the annealing temperature plays a key role in the performance of NMC-AT samples in the ORR. Although the NMC-AT-1000 sample shows the highest ORR activity as a metal-free electrocatalyst among the NMC-AT and other samples (Table S2†), the onset, half-wave potentials, and current density are slightly smaller than those of Pt/C (0.93 V vs. RHE, $E_{1/2}$ = 0.81 V and J_L = 5.34 mA cm⁻²).

LSV curves of NMC-AT-1000 were obtained at a scanning rate of 5 mV s⁻¹ and various rotating speeds (400–1600 rpm) to clarify the reaction kinetics. As shown in Fig. 4, the current density is enhanced with the increase in the rotation rate, which is attributed to the facilitation of electrolyte diffusion. The potential dependent rate constant of the ORR was analyzed using the Koutecky–Levich equation for a more quantitative analysis. The K–L plot shown in Fig. 4c displays good linearity, exhibiting a first-order reaction kinetics. From the slopes of the K–L plots, it is observed that the sample NMC-AT-1000 exhibits a direct 4e⁻ ORR process. Fig. 4d displays the number of electrons calculated at reaction potentials of 0.5, 0.55 and 0.6 V, which indicates that all the electron transfer numbers are close to 4. Moreover, the kinetic current density (J_k) calculated for the sample NMC-AT-1000 from the K–L plot at 0.55 V vs. RHE is 33.1 mA cm⁻², which is higher

Fig. 4 (a) LSV curves obtained at 10 mV s⁻¹ and 1600 RPM. (b) LSV curves obtained at 5 mV s⁻¹ and different speeds. (c) K–L plot derived from LSV curves. (d) Number of electrons calculated at different potentials. (e) EIS spectra of NMC-AT samples. (f) Methanol tolerance of the NMC-AT-1000 sample and Pt/C.

than that of Pt/C.⁵¹ In addition, the Tafel slopes of all the samples were analyzed to understand the kinetics and the plot is displayed in Fig. S7.† The results show that NMC-AT-1000 has a Tafel slope of 82 mV dec⁻¹ which is the lowest among samples like NMC-AT-900 (104 mV dec⁻¹), NMC-AT-800 (109 mV dec⁻¹) and NMC-AT-1100 (109.8 mV dec⁻¹). The lower Tafel slope suggests that the ORR in NMC-AT-1000 proceeds in a faster kinetic way.

Electrochemical impedance spectroscopy (EIS) is further conducted to compare the reaction kinetics of different NMC-AT samples. It can be observed from Fig. 4e that the Nyquist plot of NMC-AT-1000 converges to a semicircle at lower potentials due to the decrease in the interfacial charge transfer resistance. Also, the lowest diameter of the semicircle indicates a lower polarization resistance in the electrochemical process compared to other samples. A similar trend was observed in the Bode plots as shown in Fig. S8.† NMC-AT-1000 exhibits a more favourable phase angle (< -20°) in the low frequency region, demonstrating the faster ion diffusion. The high specific surface area and porosity of NMC-AT-1000 enhanced the reactant adsorption, consequently reducing the activation energy and promoting a more efficient reaction. Furthermore, the durability test was carried out to understand the stability and tolerance of the electrocatalyst. The methanol tolerance of NMC-AT-1000 was determined by adding 3 M methanol into the 0.1 M KOH electrolyte. As shown in Fig. 4f, no significant change was noticed in the current density of the

NMC-AT-1000 sample before and after the addition of methanol at 0.50 vs. RHE. In contrast, the current density of the Pt/C catalyst exhibits a sharp decrease with the addition of CH₃OH. From these results, it can be concluded that NMC-AT-1000 emerges as a promising candidate for methanol fuel cells with stability exceeding 15 000 seconds, especially considering the inadequate performance of commercial Pt/C. The presence of a high specific surface area, a large pore volume and the structural defects caused by doping nitrogen favoured a better performance in NMC-AT-1000. In addition, the high catalytic activity of NMC-AT-1000 towards the ORR indicates that the presence of optimum pyridinic and pyrrolic N as active sites together with high crystallinity and a larger micropore area and pore volume plays a key role in reducing oxygen through a 4e⁻ pathway.

DFT calculations were further used to investigate the ORR mechanism and the synergistic effects of NMC-AT samples. The feasible geometrical structure of NMC-AT was modelled by considering a 7 × 7 supercell of graphene. In graphene, two carbon atoms were removed to resemble the monolayer of the carbon material and five carbon atoms were replaced by nitrogen atoms to represent the NMC-AT samples. Based on the experimental results obtained from FTIR, XPS and NEXAFS, the model chooses two pyrrolic-N, two pyridinic-N and one graphitic-N atom in the NMC-AT samples. The structure for NMC-AT was modelled and optimized without imposing any constraints, and the finalized structure is visualized in Fig. 5a.

Fig. 5 (a) Optimized structure of NMC-AT. (b) Representation of carbon atoms with higher positive charge in NMC-AT samples (yellow: 0.879e, red: 0.4 to 0.5e, green: 0.3 to 0.39e, pink: 0.2 to 0.29e, cyan: 0.1 to 0.19e). (c) Possible models of O₂ molecule adsorption orientation on NMC-AT. (d) Electrochemical ORR 4e⁻ pathway energy profile of NMC-AT.

The adsorption of O₂ is considered one of the important characteristics of ORR activity. Hence, the most feasible O₂ adsorption sites and their adsorption energy on NMC-AT were calculated. Utilizing Bader charge analysis, four higher positive charge sites in the NMC-AT have been identified and predicted. The schematic representation of the carbon atoms with positive charge sites in the optimized NMC-AT structure is displayed in Fig. 5b. The O₂ molecule has been allowed to interact with the positive sites of the NMC-AT, as shown in Fig. 5c. There are four possibilities for O₂ adsorption. Model 1 is the O₂ molecule attached to the carbon adjacent to the pyridinic N, Model 2 is the O₂ molecule attached to the carbon ring structure, Model-3 is the O₂ molecule attached to the C1 site of pyrrolic N, and Model-4 is the O₂ attached to the C4 site of pyrrolic N. The calculated adsorption energies of Model-1, Model-2, Model-3 and Model-4 are −1.8, −1.56, −1.4 and −0.96 eV, respectively. A higher O₂ adsorption energy was observed in Model I, indicating that the O₂ molecule is most likely to adsorb onto the second most positively charged site of the NMC-AT sample. Moreover, the calculated adsorption energy of all the positive charge sites in NMC-AT is negative, demonstrating that carbon atoms around the nitrogen atoms act as active sites for O₂ adsorption. The carbon atoms have higher adsorption energy, which promotes O₂ adsorption and, hence, the ORR efficiency. The experimental findings of the ORR proved that the NMC-AT samples are undergoing a 4e[−] pathway oxygen reduction. The DFT calculations reveal that the framework of NMC-AT paves the way for efficient ORR activity.

The 4e[−] ORR pathway and possible intermediate formation during the ORR of electrocatalytic NMC-AT samples were investigated using DFT calculations. The typical 4e[−] ORR pathway has been considered for the calculation.

Here, * indicates the active catalyst NMC-AT and the intermediate species with * indicates that the species are adsorbed on the NMC-AT. The schematic ORR pathway and the energy profile of the NMC-AT are shown in Fig. S9† and Fig. 5d. In Step 1, the O₂ molecule is adsorbed on the electrocatalytic NMC-AT surface with the adsorption energy of −1.8 eV. The adsorption energy indicates that this step is most feasible, and the O₂ is readily adsorbed on the NMC-AT surface. After the adsorption, the bond length between oxygen atoms in the O₂ molecule increases from 1.16 Å to 1.23 Å, demonstrating the interaction between the O₂ molecule and NMC-AT and weakening the O₂ bond order. Step 2 represents the O₂ hydrogenation, and in this process, the bond length between the O₂ molecules increases from 1.23 Å to 1.36 Å and the relative energy is calculated as −2.6 eV. The observed results indicate that the O₂

hydrogenation process is more feasible. Step 3 denotes the hydrogenation process, where OOH and H split into two OH radicals and adsorb on the NMC-AT surface. This process is an uphill process as compared to Step 1 and Step 2. The negative energy indicates that the process is feasible; however, the process slows down the overall ORR activity and acts as a rate-determining step. In Step 4, an H₂O molecule is formed by the hydrogenation process and desorbed from the NMC-AT surface. During the final hydrogenation process (Step 5), two H₂O molecules are formed and desorbed from the NMC-AT surface. The energy profile indicates that both Step 4 and Step 5 are feasible; however, they have slightly higher uphill nature than Step 2. The DFT calculations revealed that the ORR 4e[−] pathway of the electrocatalytic NMC-AT is feasible, and the formation of two OH radicals acts as a rate-determining step for the overall ORR activity.

4. Conclusion

In summary, we demonstrated the synthesis of a mesoporous nitrogen-doped porous carbon material with a tunable nitrogen content using a high nitrogen-containing precursor, amino-triazine, by simply modifying the annealing temperature and its application in the oxygen reduction reaction. From XPS and NEXAFS analysis, it was found that the optimum doping of pyridinic and pyrrolic N into the mesoporous nitrogen-doped porous carbon material can be achieved at 1000 °C (NMC-AT-1000). Among the samples prepared, NMC-AT-1000 exhibited improved ORR activity with an onset potential of 0.87 V vs. RHE, a half-wave potential of 0.78 V vs. RHE and a high diffusion-limiting current density (*J_L*) of 5.1 mA cm^{−2}. We also demonstrated that the nitrogen-doped carbon species promote ORR activity and improved four-electron selectivity. The high specific surface area, large pore volume and high doping concentration of nitrogen helped to increase the number of active sites required for improving the ORR activity. The DFT calculations suggested that the high ORR activity in NMC-AT-1000 is attributed to its structural and planar defects, which modulate the surface electronic properties of the electrocatalyst, leading to a reduction in the energy barrier for the ORR. The present work highlights the importance of using a triazine-based precursor modulated mesoporous N-doped porous carbon as an efficient catalyst for ORR and a potential replacement for expensive Pt-based catalysts, making it suitable for metal–air batteries and fuel cells.
