Tuning SpyTag–SpyCatcher mutant pairs toward orthogonal reactivity encryption†

Yajie Liu,^{‡a} Dong Liu,^{‡a} Wei Yang,^{‡b} Xia-Ling Wu,^{IDa} Luhua Lai^{ID*ac}
and Wen-Bin Zhang^{ID*ad}

Genetically encoded covalent peptide tagging technology, such as the SpyTag–SpyCatcher reaction, has emerged as a unique way to do chemistry with proteins. Herein, we report the reactivity engineering of SpyTag–SpyCatcher mutant pairs and show that distinct reactivity can be encrypted for the same reaction based on protein sequences of high similarity. Valuable features, including high selectivity, inverse temperature dependence and (nearly) orthogonal reactivity, could be achieved based on as few as three mutations. This demonstrates the robustness of the SpyTag–SpyCatcher reaction and the plasticity of its sequence specificity, pointing to a family of engineered protein chemistry tools.

Introduction

In recent years, covalent peptide tagging technology has attracted numerous research interests as a “molecular superglue” possessing “infinite” affinity to protein partners.^{1–5} Based on isopeptide-forming pilin subunits,⁶ a few reactive pairs have been developed, including isopeptag-N and pilin-N,⁷ SpyTag and SpyCatcher,⁸ SnoopTag and SnoopCatcher⁹ and SdyTag and SdyCatcher.¹⁰ Such reactions are considered genetically encodable, allowing one to program the post-translational modification of proteins in cells and expand the protein backbone topology beyond the linear configuration.^{11–13} Not only have cyclic, tadpole-like and other branched proteins been prepared,¹¹ but direct cellular syntheses of protein catenanes and star proteins have also been demonstrated.^{12,13} Covalent tagging is thus an “iron grip” for synthetic biology,⁵ offering tremendous opportunities in applications such as preparing all-protein-based hydrogels,¹⁴ making “living” materials,¹⁵ engineering synthetic vaccines,¹⁶ controlling protein cellular locations¹⁷ and membrane protein activity¹⁸ and enhancing sortase efficiency.¹⁹ The extraordinary reactivity of SpyTag–SpyCatcher

chemistry is reminiscent of “click” chemistry in materials science.²⁰ Nevertheless, unlike functional groups in synthetic molecules, whose reactivity is defined mostly by their intrinsic properties, the reactivity of such peptide–protein pairs is instead defined by sequences and the resulting folded structures. Such a prerequisite precludes its application in nonaqueous environments or other denaturing conditions, but it also promises a family of peptide–protein reactive pairs with diverse features, distinct specificity and stimuli-responsive reactivity based on the same structural scaffold.²¹ In other words, even for the same reaction, the reactivity might be encoded orthogonally. In this contribution, we report the rational design and directed evolution of SpyTag–SpyCatcher reactive pairs toward orthogonal reactivity with sequences of high similarity (Fig. 1). We show that valuable features, including high selectivity, reversed temperature dependence and (nearly) orthogonal reactivity, could be achieved on the SpyTag–SpyCatcher scaffold with as few as three mutations.

Results and discussion

Evolving the reactive pairs

Directed evolution is a powerful technique in protein engineering to improve protein stability and to adapt proteins to new substrates, as well as to create new protein functions.^{22–24} The key lies in the generation of genetic diversity and the identification of protein variants with the desired properties.²⁵ To date, no methods have been developed to direct the evolution of chemically reactive peptide–protein pairs. This is non-trivial, as this is a two component system and it is not easy to distinguish chemical bonding from strong physical association under the normal conditions used for screening. It was reported that the SpyTag–SpyCatcher reaction allowed the *in vivo* cyclization of an elastin-like protein (ELP) (AB).¹¹ We envisioned that

Fig. 1 (A) Directed evolution of the SpyTag–SpyCatcher reactive pairs by sequential site-saturation mutagenesis and reactivity assay by SDS-PAGE analysis. (B) Crystal structures of the SpyTag and SpyCatcher complex (PDB: 4MLS). SpyTag is shown in pink and SpyCatcher is shown in green. The catalytic isopeptide triad is shown as pale sticks, the three key mutation sites are colored orange, and the other key residues in the hydrophobic pocket are colored blue. (C) By considering SpyTag as the key and SpyCatcher as the lock, we aimed to find a master key that can open all locks (*i.e.* forming covalent isopeptide bonds) and a pair of orthogonal sub-keys/sub-locks.

the ratio between cyclized (c-AB) and linear (l-AB) proteins, as shown in SDS-PAGE, would represent their reactivity under the conditions of expression (*i.e.* 16 °C in *Escherichia coli*) (Fig. 1A). Although this is not a high throughput method, it still provides a convenient way to screen the variants' reactivity.

To begin with, we targeted the key residues within 5 Å around SpyTag in the complex (PDB: 4MLS) as the protein–protein interaction interface, which is critical for tuning the specificity and efficiency of the reactive pairs (Fig. 1B). To generate genetic diversity, we performed sequential focused site-saturation mutagenesis on each of them.²⁶ In the first round, we introduced mutations onto SpyTag at the position of isoleucine (Ile3) to abolish its reactivity. The I3W mutant was found to yield almost exclusively the linear product, indicating poor reactivity (Fig. S1†). Based on this, we constructed a library of variants for restored reactivity in the subsequent rounds of directed evolution (see Fig. S1 and Table S1† for typical screening results). Finally, we found that a F77V, F94A mutant of SpyCatcher (B_{VA}) partially restores the reactivity with A_W (Table S1†). Using this strategy, we aimed to achieve orthogonal reactivity encryption within the same protein scaffold with as few mutations as possible. If we make an analogy between the SpyTag–SpyCatcher reaction and the “lock-and-key” concept, we hope to find a master key that opens all locks (*i.e.* forming

isopeptide bonds), and a pair of orthogonal sub-keys/sub-locks for selective functionalization (Fig. 1C).

In vitro reactivity assay

To gain a full picture of the reactivity profile between the SpyTag mutants and the final SpyCatcher mutant (B_{VA}), the SpyTag mutants were individually fused with a green fluorescent protein (A_X-GFP), where X stands for the mutated amino acid (see Fig. S2 for the sequences and S3 for the mass spectra†). SpyCatcher (B) and the final mutant, B_{VA}, were also cloned and expressed separately (see Fig. 2 and S4 for the sequences and S5 for the mass spectra†) for *in vitro* reactivity assay with A_X-GFP.

The reaction was carried out in PBS at pH 7.4, at different temperatures, at a concentration of 40 μM for A_X-GFP and 80 μM for B or B_{VA}. The kinetics were followed by taking aliquots at designated times and the yields were determined by SDS-PAGE and gel densitometry (Fig. 3 and S6–S12†). In general, the SpyTag–SpyCatcher reaction remains the best of its kind. Mutations on either side seem to compromise the reactivity. The kinetics toward B are slowed down slightly from A-GFP to A_F-GFP, more significantly from A-GFP to A_W-GFP, and dramatically from A-GFP to A_W-GFP. For B_{VA}, the trend is similar, but the kinetics are much slower than those for B. Surprisingly, its reactivity is almost nullified toward A_Y-GFP, but is restored toward A_W-GFP, even though the side chain of Trp is considerably larger. Specifically, we compared the results after reaction at 4 °C for 5 hours, as shown in Fig. 3A. SpyTag behaves like a master key with excellent reactivity toward both B and B_{VA}. The mutant's reactivity toward SpyCatcher drops upon increasing the size of the side chains. Eventually, the yield between A_W-GFP and B is merely ~39%. While B_{VA} retains full reactivity with A-GFP, the yield drops to 47% for A_F-GFP and 14% for A_Y-GFP, but rises again to 60% for A_W-GFP. The trend of reactivity is consistent with the *in vivo* cyclization results, but the yields seem a little higher because we purposely used a higher concentration of reactants and an excess of B or B_{VA} to

Fig. 2 Amino acid sequence alignments of SpyTag, SpyCatcher and their mutants. Key mutations are colored yellow. The secondary structure of the SpyTag–SpyCatcher complex (PDB: 4MLS) is shown for comparison. The picture was generated by ESPript 3.0.

Fig. 3 (A) SDS-PAGE analysis of the reaction products of A_X -GFP and B_{VA} at 4 °C for 5 hours; (B) yields after reaction at 4, 16, 25 and 37 °C for 5 hours.

drive the reaction forward. The possibility to manipulate the reactivity by the experimental conditions is an advantage for *in vitro* experiments. Interestingly, the temperature dependence of the reactivity is completely opposite for B and B_{VA} (Fig. 3B and S6[†]). This is best demonstrated in their reactions with A_W -GFP. For B, the yield increases and plateaus at higher temperatures, but for B_{VA} , the yield is promoted at lower temperatures. This suggests that they may have different mechanisms for reconstitution and reaction. From the current data, we deduced that (i) B_{VA} exhibits selective reactivity with A, but not A_Y , whereas A_Y reacts well with B; (ii) at lower temperatures, A_W would preferentially react with B_{VA} , while A_Y would selectively react with B, which is close to orthogonal.

To examine the selectivity of these mutant pairs, we designed a series of experiments. In the first one, elastin-like proteins (E) bearing A_Y (or A_W) at the N-terminus and A (or A_Y) in the middle of the chain were designed ($A_{X1}EA_{X2}E$), as well as their nonreactive controls, where the reactive Asp in either one of the SpyTag variants was changed to Ala ($A_{X1}'EA_{X2}E$ or $A_{X1}EA_{X2}'E$) (Fig. S13–S16[†]). There are two possible pathways for their reaction with SpyCatcher and its mutant. Depending on the first reaction site, this would lead to type I and II intermediates (Fig. 4A). If selectivity permits, sequential functionalization could be performed on one protein scaffold to give distinct di-adducts. By design, the nonreactive mutants will trap the reaction at different intermediate states as controls. The second design was to use a B_{VA} -functionalized cyan fluorescent protein (CFP- B_{VA}) to selectively fish out the right tag from a pool of telechelic proteins containing different SpyTag mutants (such as A_X -GFP and SUMO- A_X) (the “tag-fishing” experiment is shown

Fig. 4 Experimental design to test the reaction selectivity and orthogonality: (A) the sequential reaction of $A_{X1}EA_{X2}E$ with B or B_{VA} may proceed through two pathways; (B) B_{VA} could selectively react with A-GFP or SUMO-A but not A_Y -GFP or SUMO- A_Y ; (C) orthogonal reactions lead to only two corresponding products from a complex mixture of reactive proteins.

in Fig. 4B and S17–S20[†]). Finally, to rigorously test the orthogonality, we mixed multiple reactive proteins in one pot and determined the product distribution (Fig. 4C).

Achieving selective reactions

Fig. 5A shows the reaction products between $A_{X1}EA_{X2}E$ and B or B_{VA} at 4 °C at 15 μ M each for 12 hours. By comparison with the control reactions, it is evident that B reacts efficiently with both A and A_Y while B_{VA} only reacts with A, but rarely with A_Y (Fig. S21[†]). The reaction using a B_{VA} -functionalized ELP (EB_{VA}) gives similar results (Fig. S21[†]). Although previous model experiments show slight residual reactivity between B_{VA} and A_Y (Fig. 3), it seems that this is inhibited tremendously in the presence of A due to the distinct kinetic difference between A and A_Y , even though A_Y is placed at a more accessible terminal site. This feature should be useful for controlling the functionalization sites and preparing proteins with complex topology. As an example, we sequentially reacted A_Y EAE firstly with B_{VA} and then with B. The size exclusion chromatography (SEC) overlay of the products at two stages clearly shows the sequential progression of the reactions (Fig. 6), and the identity of the products was corroborated by MALDI-TOF mass spectra and SDS-PAGE analysis (Fig. S22 and S23[†]). This excellent

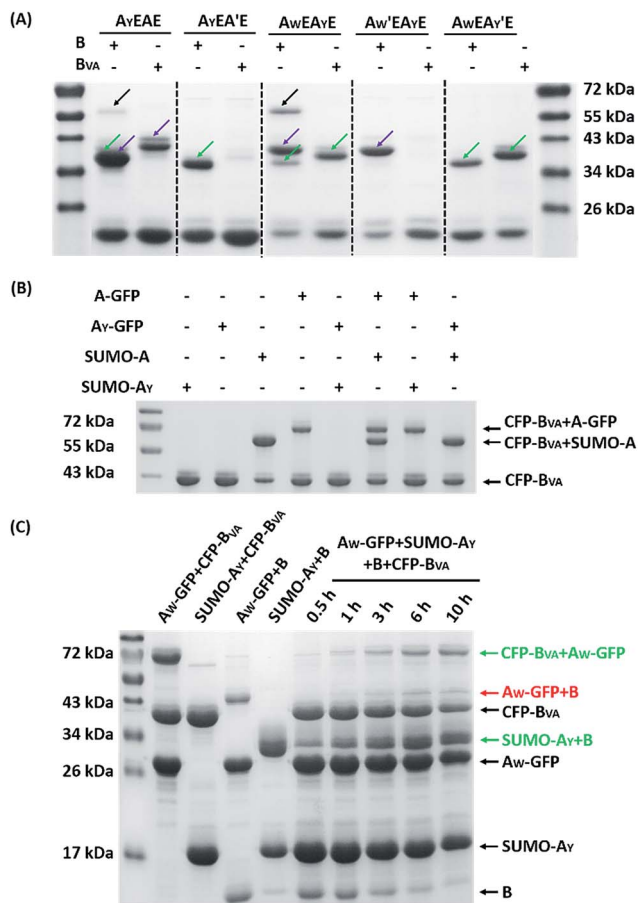

Fig. 5 (A) SDS-PAGE analysis of the reaction products of $A_{X1}EA_{X2}E$ and B or B_{VA} at 4 °C for 12 hours ($[A_{X1}EA_{X2}E] : [B \text{ or } B_{VA}] = 15 \mu\text{M} : 15 \mu\text{M}$); the green arrows point to the type I mono-adduct, the purple arrows point to the type II mono-adduct, and the black arrows point to the di-adduct. (B) SDS-PAGE analysis of the reaction products between CFP- B_{VA} and a mixture of proteins containing SpyTag or its mutant ($[CFP-B_{VA}] : [A_X-GFP \text{ or } SUMO-A_X] = 30 \mu\text{M} : 30 \mu\text{M}$). No reaction occurred between CFP- B_{VA} and any protein containing A_Y . (C) SDS-PAGE analysis of the products from the one-pot reactions in a mixture of A_W -GFP, SUMO- A_Y , CFP- B_{VA} and B at different times at 4 °C ($[CFP-B_{VA} \text{ or } B] : [A_W-GFP \text{ or } SUMO-A_Y] = 30 \mu\text{M} : 60 \mu\text{M}$). The cross-reaction product formed at later stages in very small amounts.

selectivity was also reflected in the “tag-fishing” experiments. We used CFP- B_{VA} to react with A_X -GFP and/or SUMO- A_X at 4 °C in PBS buffer (pH 7.4) in a 1 : 1 molar ratio at a concentration of

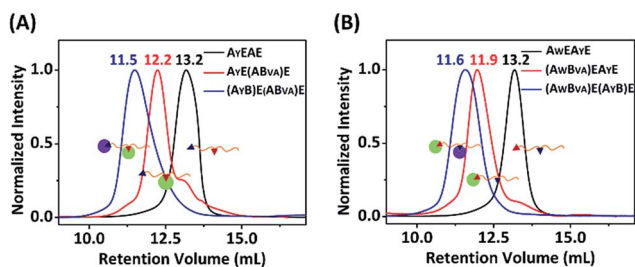

Fig. 6 SEC overlay of the products at each stage from the sequential reaction of A_YEAE (left) or A_WEA_YE (right), firstly with B_{VA} and then with B. The numbers above the peaks denote the retention volume of each peak.

30 μM each for 5 hours. The SDS-PAGE analysis clearly shows that no products formed from a mixture of CFP- B_{VA} with any A_Y -containing protein, whereas a mixture of CFP- B_{VA} with any SpyTag-containing protein yielded the corresponding products (Fig. 5B and S24A[†]). The ability to distinguish the reactivity of peptide tags that differ by only one amino acid is remarkable.

Tuning toward orthogonal reactions

The ability to encode information about chemical reactions into protein sequences greatly adds to the diversity of reactions and reactivity control. Even for the same type of reaction, there may be multiple, mutually orthogonal ways for reactivity encryption. While reactive pairs developed from completely different domains are intrinsically orthogonal to each other, orthogonality may also arise from the same ancestor domain.

Since A_W and A_Y possess opposite reactivity to B and B_{VA} , we proceeded to examine how orthogonal they are to each other. We firstly reacted A_WEA_YE , as well as the $A_WEA'_YE$ and $A_WEA_Y'E$ controls, with B or B_{VA} at 4 °C for 12 hours, at a molar ratio of 1 : 1 with a concentration of 15 μM each, and analyzed the results by SDS-PAGE. It was clear that both A_W and A_Y are reactive toward B, and there are two bands for the mono-adducts and one for the di-adduct (Fig. 5A). By comparison of the products with the controls, we deduced that the lower band of the mono-adducts is the type I mono-adduct and the higher band is the type II mono-adduct. There is a much higher selectivity for A_Y in the middle over A_W at the chain end. Considering that the terminal location of A_W is kinetically much more advantageous, the intrinsic selectivity for A_Y should actually be even higher. To prove this, we constructed A_YEA_WE and reacted it with B or B_{VA} under identical conditions. The results show that the reaction of A_YEA_WE with B gives almost exclusively the type I product and very little di-adducts, indicating a very high selectivity (Fig. S21C[†]). On the other hand, for B_{VA} , the selectivity for A_W over A_Y is excellent. No products form from the reaction between A_Y and B_{VA} at all, while the yield from the reaction between B_{VA} and A_W is decent for A_WEA_YE when A_W is at a terminal site, and poor for A_YEA_WE when A_W is in the middle (Fig. S21C[†]). The good selectivity encouraged us to also pursue sequential functionalization on A_WEA_YE , firstly with B_{VA} and then with B. The products at each stage were characterized by MALDI-TOF mass spectra and SEC (Fig. 6, S22 and S23[†]). The results are similar to the previous case, except that the intermediate is a type I mono-adduct in this case instead of a type II mono-adduct. The two intermediates have different retention volumes, with type I being smaller (11.9 vs. 12.2 mL). This is consistent with the expanded linear-chain-like topology of the type I mono-adduct and the compact star-like topology of the type II mono-adduct, confirming again the highly selective functionalization.

A strict evaluation of the orthogonality would be from multiple reactants in one pot. It was hoped that the reactions would proceed in parallel in one pot without mutual interference. We thus mixed A_W -GFP, SUMO- A_Y , CFP- B_{VA} and B at a concentration of 30 μM for the SpyCatcher variants and 60 μM for the SpyTag variants at 4 °C. Control reactions were run by

mixing only two reactive proteins under identical conditions (Fig. 5C, lanes 2–5). A time course for the one-pot reaction was recorded (Fig. 5C, lanes 6–10). This clearly shows that the major products are the desired products, CFP-B_{VA}:A_W-GFP and B:SUMO-A_Y. There is only very little cross-reacted product of B:A_W-GFP appearing at the late stages (~6 hours). No cross-reacted product of CFP-B_{VA}:SUMO-A_Y was observed (Fig. S24†). Therefore, A_W/B_{VA} and A_Y/B could be viewed as two mutant pairs with nearly orthogonal reactivity at shorter times and lower temperatures. Even considering the product distribution after 10 hours of reaction, B still has ~9.1-fold selectivity for SUMO-A_Y over A_W-GFP, and A_W-GFP still exhibits ~5.5-fold selectivity for CFP-B_{VA} over B. Considering that the two reactive pairs only differ by three amino acids, this result is impressive. It is also worth noting that the reactivity may vary depending on the location of the reactive domains and the 3D structure of the fusion proteins, which may or may not promote the selectivity of the reactions.

To understand the reaction selectivity, we built structural models of the mutant pairs using RosettaDesign (Fig. S25†).^{27,28} When the I3W mutation is introduced into SpyTag, the bulky side chain of Trp clashes with the original residues on B, which leads to a calculated binding free energy as high as 534.99 REU (Rosetta energy units, an arbitrary energy unit based on the Rosetta score function).²⁹ By changing the two Phe residues on B to smaller residues (Val and Ala), B_{VA} could better accommodate the Trp residue of A_W, as demonstrated by the much lower calculated binding free energy of -36.14 REU for A_W:B_{VA}. On the other hand, the I3Y mutation in SpyTag retains its reactivity with SpyCatcher by forming good hydrophobic interactions between A_Y and B with a packing score of 0.758,³⁰ while the interactions between A_Y and B_{VA} are significantly deteriorated, as reflected by the much lower packing score of 0.683. Although the detailed molecular mechanism affecting the reactivity remains to be illustrated by techniques like crystallography, the trend predicted by computational studies is generally consistent with the experimental results. Aided by computational studies and rational design, we are continuing to improve the orthogonality and reactivity of the mutant pairs along this line.

Conclusions

In summary, we have developed mutants of SpyTag–SpyCatcher reactive pairs with engineered reactivity and selectivity through directed evolution. With only two mutations, B_{VA} exhibits distinct reactivity profiles compared to B. The inverse temperature dependence of the reactivity suggests that they may adopt different reconstitution mechanisms. SpyTag is like a master key, reactive with both B and B_{VA}. A_Y is like a sub-key that only “opens” the lock B rather than B_{VA}. In contrast, A_W possesses dramatically reduced reactivity with B but still exhibits decent reactivity with B_{VA} at lower temperatures. The reactivity between A_Y/B and A_W/B_{VA} is thus close to orthogonal with some minor cross-reaction between A_W and B. Although the promiscuity is not completely removed, the ability to engineer reactivity with minimum sequence variation (as few as three mutations) opens up new avenues in the ever-expanding “iron grip” toolbox for

synthetic biology. It also promises a family of genetically encoded and engineered peptide–protein chemistry tools, much like what the fluorescent protein family has offered to the community.
