Pseudopeptides based on the kallikrein-related peptidase 3 (KLK3) activating bicyclic peptide "C-4" comprising hydrocarbon-based disulphide bridge mimetics have been synthesized. After investigating different synthetic approaches, the pseudopeptides were successfully cyclized from two L-allylglycine side chains via an alkene ring-closing metathesis reaction during the peptide synthesis. The alkene-linker was formed in a 1 : 1 E/Z isomer ratio. The resulting pseudopeptides were almost as potent as the parent peptide, increasing the activity of KLK3 over four-fold at 200 $\mu\text{g ml}^{-1}$ (130–140 μM) concentrations.

Introduction

The human kallikrein-related peptidases, a family of 15 closely related serine proteases (KLK1–KLK15), are attracting increased attention due to their role as biomarkers for screening, diagnosis, and monitoring of various cancers.¹ Among these KLK3, also known as prostate-specific antigen (PSA), is the most studied. It has been shown to be highly prostate specific and there is growing evidence supporting its use for targeted treatment and selective imaging of prostate cancer.^{2,3} In prostate cancer, the KLK3 expression is reduced and more aggressive tumours have lower KLK3 levels than less aggressive ones.^{4–6} At the same time the levels of KLK3 in blood are elevated due to increased leakage from the prostate, however, in blood circulation the majority of KLK3 is rapidly inactivated by endogenous protease inhibitors.⁷ KLK3 exerts an antiangiogenic activity that is related to its enzymatic activity.^{8–10} It has therefore been suggested that tumour angiogenesis and thus prostate cancer growth might be controlled by increasing the proteolytic activity of KLK3.^{9,11}

Peptide 1 (C-4), developed by Stenman and coworkers, is so far the most potent KLK3 activating compound,¹² increasing the proteolytic activity of KLK3 several-fold at micromolar concentrations (Table 3). Interestingly, all known potent compounds

having this unique biological activity are peptides.¹¹ Peptide 1 is likely to bind near the active site of KLK3, as the binding could be inhibited by monoclonal antibodies binding close to the active site.¹² Recent studies demonstrate that peptide 1 enhances the antiangiogenic activity of KLK3 in an endothelial cell tube formation assay.¹³

Peptide 1 consists of 13 amino acids and is cyclized by two disulphide bridges, one between Cys-1 and Cys-13, and one between Cys-5 and Cys-10. The side chains of Tyr-4, Ile-6 and Trp-11 have previously been identified to be important for their biological activity.¹⁴ As these amino acid residues are directly attached to the central disulphide bridge, this part of the peptide was considered to be most important for the development of pseudopeptides of 1. *In vivo* stable replacements of the central disulphide bridge would result in pseudopeptides with new molecular backbones.

We have earlier reported the successful synthesis of a series of orthogonally protected disulphide bridge mimetics (2a–d),¹⁵ and in the present study our aim was to synthesize pseudopeptides of peptide 1 with these mimetics as replacements for the centrally positioned disulphide bridge. As described earlier, 2a–d can easily be converted to 3a–d, which have a more suitable combination of protecting groups for solid phase peptide synthesis using Fmoc-chemistry.

An additional objective was to identify all important side chains in 1 using multiple alanine replacements. In our earlier single alanine replacement study the importance of other amino acid side chains except Tyr-4, Ile-6 and Trp-11 was not fully determined.¹⁴ As the pseudopeptides are cyclized in a way that gives them a new backbone, we wanted to clarify if some parts of the original peptide structure could be simplified without decreasing the biological activity.

Results and discussion

Identification of all important amino acid side chains in peptide 1

We started the current study by performing simultaneous substitutions of more than one amino acid residue with alanine on peptide 1. The peptides were synthesized on a peptide synthesizer using Fmoc-chemistry on Rink AM resin, resulting in peptides with a C-terminal amide instead of the C-terminal carboxylic acid. This difference has however no significant influence on the biological activity (unpublished data). The effect of the peptides on the proteolytic activity of KLK3 was tested *in vitro* using a chromogenic peptide substrate according to a published procedure (Table 1).¹⁶

Although the original single alanine replacement study indicated that residues Glu-7, His-8 and His-9 could all be replaced with alanines, His-9 was found to be necessary for retaining full activity when two or three of these residues were replaced with alanines at the same time (peptides 4–7).

Table 1 Synthesized analogues of peptide 1, and their effects at 20 $\mu\text{g ml}^{-1}$ (13–15 μM) concentration on the proteolytic activity of KLK3, the amino acid replacements are marked in bold face (the activity of KLK3 alone is 100%)

Furthermore, replacing Cys-5 and Cys-10 with alanines in combination with replacing Ile-6 and His-9 with cysteines to form the centrally positioned disulphide bridge resulted in an inactive peptide (peptide 8). Interestingly, Val-2 and Thr-12 could not be replaced simultaneously with alanines (peptide 9). Thus, the amino acids directly connected to the cysteine residues of both disulphide bridges seem to have a significant influence on the biological activity of 1.

The identified important side chains can either have direct interactions with the binding site on KLK3 or have a critical influence on the biologically active conformation of the peptide. According to a recent report, the binding site of 1 was suggested to be located in the kallikrein loop region on KLK3,¹⁷ which makes the analysis of the binding site more challenging due to the flexibility of the loop region.

Ile-6 was also replaced with different non-polar amino acids (peptides 10–13). Interestingly, this residue could be replaced with phenylalanine and leucine, which both have lipophilic side chains of similar size to that of isoleucine. However, considerably smaller amino acids such as glycine or alanine were not successful replacements.

Synthesis and evaluation of the pseudopeptides

The pseudopeptides were designed based on our previously reported disulphide bridge mimetics 2a–d/3a–d.¹⁵ The three most potent peptides, original peptide 1 and analogues 5 and 10, were used as starting peptides in this part of the study. Peptide 5 was of primary interest due to its lower molecular weight. The pseudopeptides were synthesized manually using Fmoc-chemistry on Cys(Acm)-preloaded Wang resin.

Our initial strategy was to use the orthogonally protected disulphide bridge mimetics 3a–d directly in solid phase peptide synthesis. However, an initial study with Fmoc-chemistry on Wang resin with mimetic 3b failed due to problems in the selective removal of the methyl ester and/or phthalimide protecting groups from the resin-bound intermediate 14 during peptide synthesis.

We also synthesized the small ring 18 with the intention of using it as an Fmoc-protected building block in solid phase peptide synthesis after hydrolysis of the methyl ester. Linear tetrapeptide 15 was straightforwardly accessed in solution starting from Boc-Ile, coupling each residue as an amino acid methyl ester and subsequently hydrolyzing the ester. The Boc and the *tert*-butyl ester groups of 2b were removed with TFA before coupling, resulting in 16. The risk for racemization in the

Scheme 1 (a) EDC·HCl, HOBT, DIPEA/MeCN, 0 °C; (b) 1.75 M HCl/EtOAc; (c) TBTU, HOBT, DIPEA/DCM, 0 °C.

coupling steps was suppressed by using EDC·HCl with HOBT and DIPEA as coupling reagents. After selectively removing the Boc-group from **17** with 1.75 M HCl in EtOAc at room temperature for 1 h followed by cyclization with TBTU, HOBT and DIPEA, **18** was obtained in good yield (42% over two steps). Although methyl ester groups can generally be selectively removed in the presence of Fmoc groups using Me₃SnOH in 1,2-dichloroethane (DCE), all our attempts to perform this reaction on **18** failed. This might be due to the steric hindrance around the ester group, from the neighbouring Trt- and Fmoc-groups (Scheme 1).

After the pioneering work by Miller and Grubbs,¹⁸ ring-closing alkene metathesis reactions on peptides have been successfully reported for a wide variety of peptides.¹⁹ This inspired us to attempt this synthetic strategy also for our pseudopeptides. However, the drawbacks with this strategy are that only the alkene-based mimetics can be accessed and that the *E/Z* ratio of the formed alkenes cannot be controlled. Peptide **19** was first synthesized using Fmoc-chemistry on Wang resin with *L*-allylglycine residues as replacements for the

cysteines in positions 5 and 10. The ring-closing alkene metathesis reaction was first attempted for cleaved **19** and resin-bound **20a** and **20b**, but all attempts were unsuccessful as the MS spectra did not reveal even trace amounts of the cyclized peptide independent of the conditions used (Table 2). Thus, as unreacted starting material was the main component in all unsuccessful reactions, the full length peptide was unreactive in the ring-closing metathesis reaction.

We refined our strategy by stopping the peptide synthesis after attachment of the second Fmoc-*L*-allylglycine, resulting in intermediate **21**. An initial attempt to perform the ring-closing metathesis on **21** using the Hoveyda–Grubbs 2nd generation catalyst (HG2) in DCE at room temperature for 48 h was unsuccessful, but in later attempts the reaction was found to be highly successful when using LiCl in DMF as an additive and performing the reaction under microwave heating at 100 °C for 60 min (Table 2). The only impurity was a trace amount of uncyclized starting material. Intermediates **22** and **23** were also cyclized successfully using the same methodology. The addition of LiCl in DMF in combination with microwave heating to enable/improve cyclization of peptides with two *L*-allylglycine residues on Wang resin by ring-closing metathesis reaction has also been presented previously by other groups.²⁰ Pre-treatment

with LiCl in DMF has also been reported to enable a similar cyclization of peptides with thermal heating (Scheme 2).²¹

There are several reported NMR spectroscopy methods for studying the *E/Z* ratio of the formed alkene.^{22,23} Product 27 (the cleaved ring-closing alkene metathesis product of 22) was studied by NMR spectroscopy according to the method reported by Bhattacharya *et al.*²² The sample was purified by preparative HPLC. The NMR spectra from the crude and purified ring-closing alkene metathesis product showed that the *E/Z* ratio was approximately 1 : 1.

As the only impurity was a trace amount of uncyclized starting material in all three cyclizations, peptide synthesis was continued on a solid support with addition of the remaining four amino acids (Tyr-4, Ala-3, Val-2 and Cys-1). The pseudopeptides were cleaved from the resin, and the AcM-protected cysteines were then deprotected and cyclized with iodine in acetic acid in the presence of aqueous HCl. The yield of the crude pseudopeptides 24, 25 and 26 were 37%, 65% and 81%, respectively. After purification by preparative HPLC to over 90% purity, the total yield for 24, 25 and 26 went down to 1%, 3% and 6%, respectively. To confirm that the purification procedure had not changed the *E/Z* isomer ratio, the NMR spectra of the purified pseudopeptide 26 showed that the *E/Z* isomer ratio was unchanged. In biological testing, the pseudopeptides 24, 25 and 26 increased the activity of KLK3 to 225%, 189% and 223%, respectively, of that of KLK3 alone at a concentration 20 μg ml⁻¹ (Table 3). The original peptide 1 increased the activity to 625%

Table 3 Effect on the proteolytic activity of KLK3 by peptide 1 and the synthesized pseudopeptides 24–26 at 20 μg ml⁻¹ concentration^a (the activity of KLK3 alone is 100%)

Pseudopeptide	KLK3 proteolytic activity [%] (mean ± SE, n = 4)
1	625 ± 36
24	225 ± 15
25	189 ± 9
26	223 ± 15

^a Corresponding to 13 μM for 1, 25 and 26, and 14 μM for 24.

Fig. 1 Effect on the proteolytic activity of KLK3 by peptide 1 and the synthesized pseudopeptides 24–26 at different concentrations.

at the same concentration. Increasing the concentration of pseudopeptides 24, 25 and 26 showed that the stimulating effect approached the level of peptide 1 at higher concentrations (Fig. 1). At 200 μg ml⁻¹ concentration they stimulated the KLK3 activity about four-fold.

In order to test if pseudopeptides with approximately half the size of the original peptide can increase the activity of KLK3, we synthesized pseudopeptides 28a, 28b and 29. Pseudopeptides 28a and 28b were synthesized according to the previously described procedure with the exception that 28a was synthesized on Trp(Boc)-preloaded Wang resin and 28b on Rink amide resin. Pseudopeptide 29 has 8-amino-octanoic acid as a replacement of the disulphide bridge and the small ring, and this linker was introduced in the peptide synthesis as an Fmoc-protected amino acid. The yield of the crude pseudopeptides 28a, 28b and 29 were 91%, 29% and 52%, respectively. After

purification by preparative HPLC to over 90% purity, the total yield for **28a**, **28b** and **29** went down to 7%, 3% and 3%, respectively. None of these smaller pseudopeptides increased the activity of KLK3 at a concentration of 20 $\mu\text{g ml}^{-1}$ (data not shown), which clearly indicates that neither ring alone is biologically active.

Conclusions

Based on the multiple alanine replacement study, we succeeded in identifying the important amino acid side chains in peptide **1**. The only non-important side chains were Glu-7 and His-8, as these could simultaneously be replaced with alanines. The multiple alanine replacement showed that most amino acid side chains are important and the size of the peptide will therefore be difficult to reduce. Furthermore, Ile-6 could be replaced with leucine and phenylalanine, which are similar in size and non-polar character.

We have developed a general synthetic route towards the pseudopeptides with a centrally positioned alkene-based disulphide bridge mimetic. However, the alkene was formed as a 1 : 1 mixture of the *E* and *Z* isomers, and the two isomers could not be separated. The same amino acid replacements that were allowed for peptide **1** were also allowed for the pseudopeptides. The most potent pseudopeptides (**24** and **26**) increased the activity of KLK3 to over 200% (doubling the activity) at a concentration of 20 $\mu\text{g ml}^{-1}$ (13–14 μM) and they were almost as potent as the parent peptide at higher concentrations, increasing the activity of KLK3 over four-fold at a concentration of 200 $\mu\text{g ml}^{-1}$ (130–140 μM). As the pseudopeptides have a new backbone consisting of the alkene-linker, we also synthesized pseudopeptides corresponding to either the small or the large ring on peptide **1**. These smaller pseudopeptides did not stimulate the KLK3 activity which indicates that it will be difficult to drastically decrease the size of the pseudopeptides.
