

Atomic layer deposition of ferroelectric LiNbO<sub>3</sub>†Cite this: *J. Mater. Chem. C*, 2013, **1**, 4283Erik Østreg,\*,<sup>a</sup> Henrik H. Sønsteby,<sup>a</sup> Timo Sajavaara,<sup>b</sup> Ola Nilsen<sup>a</sup> and Helmer Fjellvåg<sup>a</sup>

The ferroelectric and electro-optical properties of LiNbO<sub>3</sub> make it an important material for current and future applications. It has also been suggested as a possible lead-free replacement for present PZT-devices. The atomic layer deposition (ALD) technique offers controlled deposition of films at an industrial scale and thus becomes an interesting tool for growth of LiNbO<sub>3</sub>. We here report on ALD deposition of LiNbO<sub>3</sub> using lithium silylamide and niobium ethoxide as precursors, thereby providing good control of cation stoichiometry and films with low impurity levels of silicon. The deposited films are shown to be ferroelectric and their crystalline orientations can be guided by the choice of substrate. The films are polycrystalline on Si (100) as well as epitaxially oriented on substrates of Al<sub>2</sub>O<sub>3</sub> (012), Al<sub>2</sub>O<sub>3</sub> (001), and LaAlO<sub>3</sub> (012). The coercive field of samples deposited on Si (100) was found to be ~220 kV cm<sup>-1</sup>, with a remanent polarization of ~0.4 μC cm<sup>-2</sup>. Deposition of lithium containing materials is traditionally challenging by ALD, and critical issues with such deposition are discussed.

## Introduction

Lithium niobate, LiNbO<sub>3</sub>, has been the centre of attention for a range of optical applications since the discovery of its ferroelectric properties in 1949.<sup>1</sup> The non-centrosymmetric trigonal structure of LiNbO<sub>3</sub> was described in detail by Nassau in 1966.<sup>2</sup> The strength of LiNbO<sub>3</sub> is its relatively large physical coefficients for piezoelectric,<sup>3</sup> pyroelectric<sup>4</sup> and photoelastic<sup>5</sup> effects. Combinations of these effects have resulted in a range of technologically important applications, including acoustic wave transducers,<sup>6</sup> optical modulators,<sup>7</sup> Q-switches,<sup>8,9</sup> optical waveguides<sup>10,11</sup> and holographic memory modules.<sup>12,13</sup> The ferroelectric response of LiNbO<sub>3</sub> has previously gathered much attention, as the theoretical intrinsic coercive fields are as high as 5420 kV cm<sup>-1</sup>. The response is attributed to the lack of inversion symmetry in the trigonal cell (SG: R3c), and is oriented along the *c*-axis. However, due to polarization gradients at 180° domain walls, reported experimental values vary from 40 kV cm<sup>-1</sup> for near stoichiometric to 210 kV cm<sup>-1</sup> for congruent composition.<sup>14</sup>

The area of ferroelectric thin films emerged in 1969 with deposition of Pb<sub>0.92</sub>Bi<sub>0.07</sub>La<sub>0.01</sub>(Fe<sub>0.405</sub>Nb<sub>0.325</sub>Zr<sub>0.27</sub>)O<sub>3</sub> by Chapman,<sup>15</sup> as a response to the need for non-volatile integrated memory devices. A range of applications have evolved over the last decades, and include microsensors,<sup>16</sup> tuneable microwave applications<sup>17</sup> and ferroresistive microelectronics.<sup>18</sup>

Undesired non-linear piezoresponse may occur in ferroelectric thin films due to domain-wall displacement. The effect has been shown to be mainly extrinsic due to manufacturing faults.<sup>19</sup> This underlines the importance of synthesis of high quality ferroelectric thin films.

Ferroelectric Pb(Zr,Ti)O<sub>3</sub> (PZT) has been the main material of choice for many applications owing to the high ferroelectric response and accessible synthetic routes. On the other hand, devices utilizing PZT, in particular when present as a nano-material, will be phased out owing to the toxicity of lead.<sup>20</sup> LiNbO<sub>3</sub> (LNO) is a possible lead-free replacement as values for the coercive field and the remanent polarization are comparable. Thin films of LiNbO<sub>3</sub> have previously been deposited by numerous techniques, such as laser ablation,<sup>21</sup> pulsed laser deposition,<sup>22</sup> molecular beam epitaxy<sup>23</sup> and sol-gel routes,<sup>23</sup> and now by atomic layer deposition (ALD). Atomic layer deposition is a proven thin film deposition technique that allows deposition of films on an industrial scale. ALD is also superior to other thin film deposition techniques with respect to uniformity and pinhole density, the latter is important for applications of ferroelectrics. An additional advantage of ALD is that it allows deposition of films on high aspect ratio structures, opening up possibilities for novel devices.

Deposition of lithium containing compounds by ALD has recently received notable attention.<sup>24–30</sup> Lithium phosphate and lithium silicate have been grown using lithium silylamide (LiN(SiMe<sub>3</sub>)<sub>2</sub> or LiHMDS) as a precursor by Hämäläinen *et al.*<sup>26,28</sup> and we have recently reported the growth of lithium nitride and carbonate by the same precursor.<sup>30</sup> Alternative types of precursors reported for deposition of lithium compounds are Li(thd)<sup>27</sup> (thd = 2,2,6,6-tetramethyl-3,5-heptadionate) and lithium *tert*-butoxide.<sup>24,25</sup> The main focus for deposition of lithium compounds by ALD has so far been towards lithium ion battery applications.

† Electronic supplementary information (ESI) available. See DOI: 10.1039/c3tc30271g

Ferroelectric lead based oxides have previously been deposited by ALD by Harjuoja *et al.*<sup>31,32</sup> while the deposition of bismuth titanates by ALD is reported by Vehkamäki *et al.*<sup>33</sup> In addition, the growth of ferroelectric yttrium doped hafnium oxide by ALD has recently been reported.<sup>34</sup> The current paper describes the epitaxial growth of ferroelectric LiNbO<sub>3</sub> by atomic layer deposition (ALD). The remanent polarization has been measured to be  $\sim 0.4 \mu\text{C cm}^{-2}$  and the coercive field is approximately  $220 \text{ kV cm}^{-1}$ .

## Experimental

Thin films were deposited in an ASM F-120 Sat ALD reactor (ASM Microchemistry Ltd) using lithium silylamide [LiN-(SiMe<sub>3</sub>)<sub>2</sub>, Me = -CH<sub>3</sub>, hereafter termed LiHMDS], niobium ethoxide [Nb(OEt)<sub>5</sub>, Et = -CH<sub>2</sub>CH<sub>3</sub>] and deionized water as precursors. LiHMDS was sublimed in an open boat at 75 °C and the niobium precursor was kept at 100 °C. All deposition processes were performed with a substrate temperature of 235 °C. Nitrogen was used as the carrier gas supplied at a total rate of  $500 \text{ cm}^3 \text{ min}^{-1}$  from a Schmidelin-Sirocco-5 N<sub>2</sub> generator providing >99.999% (N<sub>2</sub> + Ar).

All LiNbO<sub>3</sub> films were deposited on soda lime glass as well as on silicon (100) wafers with native oxide. Selected deposition processes were made on single crystals of Al<sub>2</sub>O<sub>3</sub> (001), Al<sub>2</sub>O<sub>3</sub> (012), SrTiO<sub>3</sub> (100) and LaAlO<sub>3</sub> (012). In order to maintain reproducible deposition, the chamber was passivated between each run with Nb<sub>2</sub>O<sub>5</sub> by supplying 2000 cycles of Nb(OEt)<sub>5</sub> and water.

X-ray diffraction analysis was performed using a Bruker AXS D8 Discover powder diffractometer and a Bruker AXS D8 Advance thin film diffractometer, both equipped with a LynxEye strip detector. The powder diffractometer has a Ge(111) focusing monochromator providing CuK<sub>α1</sub>-radiation. The thin film diffractometer was equipped with a Göbel mirror and a Ge(220) four bounce monochromator for X-ray reflectivity (XRR) measurements and reciprocal space maps of symmetric reflections, whereas only a Göbel mirror was used for reciprocal space maps of asymmetric reflections. X-ray reflectivity data were analysed using the GenX software.<sup>35</sup>

A J. A. Woolam  $\alpha$ -SE spectroscopic ellipsometer was used to determine the thickness and refractive index from data measured in the range 380–900 nm. The films were assumed transparent and the data were fitted using a Cauchy-model.

Time of flight elastic recoil detection analysis (TOF-ERDA) measurements were performed at the University of Jyväskylä using a 8.515 MeV <sup>35</sup>Cl<sup>4+</sup> beam from the 1.7 MV Pelletron accelerator. With this technique all the sample elements, including impurities above 0.1 at% concentration could be quantified. The only exception is Si, which was partly shadowed by the strong signal of <sup>35</sup>Cl scattered from Nb. Scanning probe microscopy measurements were performed using a Park Systems XE-70 unit. Atomic force microscopy (AFM) measurements were performed in contact mode using a CONTSCR tip while the piezoresponse force microscopy (PFM) measurements were performed using a PPP-NCSTAu 3M gold plated silicon tip (Nanosensors) and an external lock-in amplifier (Standford Research Systems).

Measurements of ferroelectric properties are made with an Aixact TF2000 analyzer at 1 kHz.

## Results

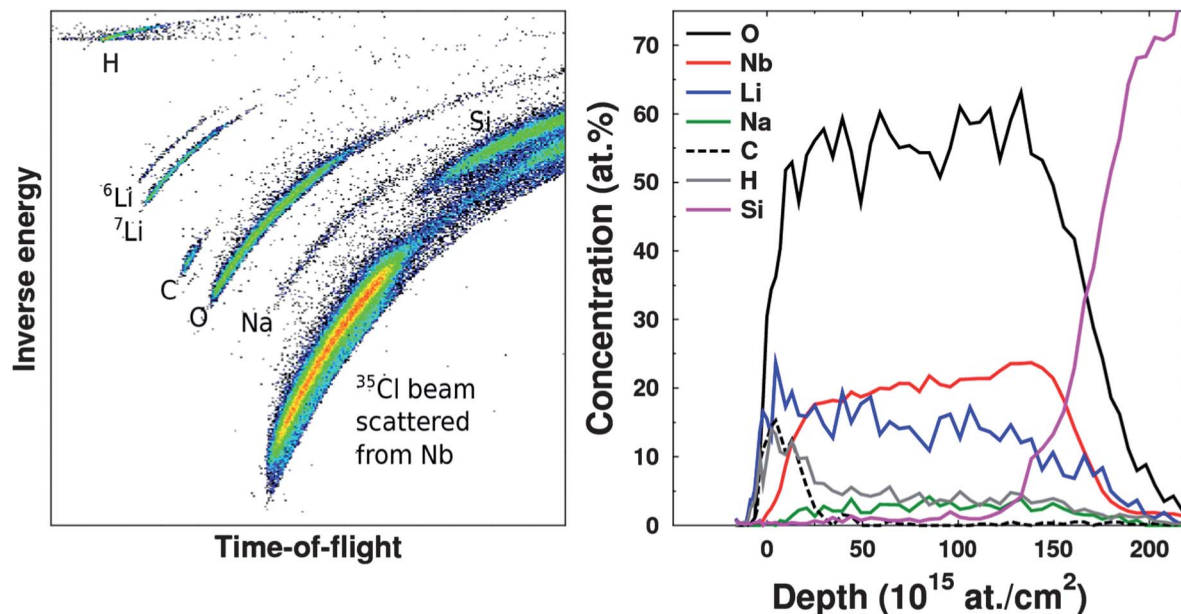

The growth of LiNbO<sub>3</sub> was studied at the deposition temperature of 235 °C using 1 s pulse and purge parameters for all precursors. For deposition of Nb<sub>2</sub>O<sub>5</sub>, these parameters gave a growth rate of 0.46 Å per cycle compared to that of about 0.3 Å per cycle which is reported by Kukli *et al.*<sup>36</sup> The growth rate was also verified through deposition in another reactor (Beneq TFS500) with the same result. The process has proven to be reproducible and shows self-limiting growth. We have adopted the same parameters for deposition of the lithium component as earlier reported for the same lithium precursor and deposition system.<sup>30</sup>

A series of samples were made by varying the lithium to niobium pulsing ratio. The total number of cycles was kept close to 2000, whereas the composition and number of the sub-cycles were varied from no lithium and up to a 1 : 1 pulsing ratio, see Table 1. For a 1 : 1 pulsing ratio of lithium to niobium, the deposition resulted in large, flame-like gradients and powder formation at the edges of the reaction chamber. It was therefore concluded that higher lithium pulsing ratios would lead to uncontrolled growth. The elemental composition was determined using TOF-ERDA, see Fig. 1 and 2. The data show the increasing lithium content with the number of lithium sub-cycles, as expected. The main impurities are sodium, carbon and hydrogen. Sodium impurities were found to be up to 3.5 at%, carbon was below 0.2 at% in most cases, except for the most

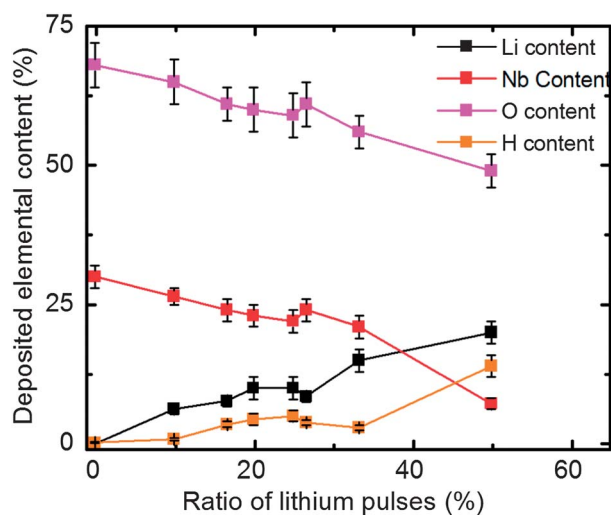

**Table 1** Summary of samples deposited using different lithium to niobium ratios

Li pulses per sub-cycle	Average Nb pulses per sub-cycle	Pulsed ratio Li/(Li + Nb) (%)	Deposited ratio Li/(Li + Nb) (%)	Thickness (nm)	Refractive index at 632.8 nm

1	1	50	73.5 ± 5.8	191.5 ± 9	1.85

**Fig. 1** A raw time-of-flight-energy histogram from a TOF-ERDA measurement (left) and the corresponding elemental depth profiles (right) of a sample deposited on a Si substrate using 666 cycles of 2 : 1 Nb to Li pulsing ratio.

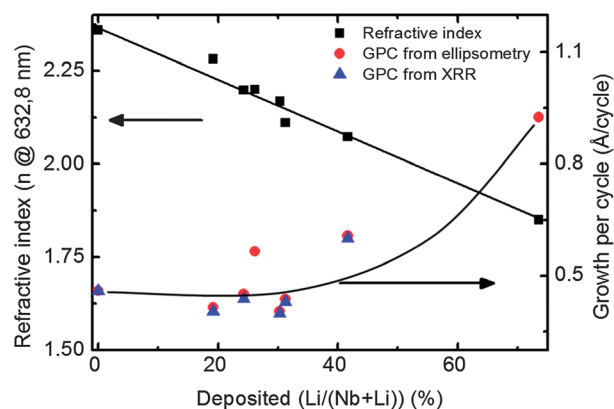

**Fig. 2** Element content in films deposited for different lithium pulsing ratios.

lithium rich sample. The amount of hydrogen appears correlated with the lithium content and exists probably as lithium hydroxide in the film. Most importantly, there is no significant amount of silicon stemming from the precursor. This proves that the cleavage of the lithium nitrogen bond in the precursor is dominant and that the precursor does not incorporate silicon in the film, consistent with what is previously reported.<sup>30</sup>

The depth profiles achieved by TOF-ERDA clearly show a carbon and hydrogen enriched layer on top of all the deposited films. This is also supported by XRR-measurement data (see ESI†). The lithium content is also higher on the surface, indicating that lithium diffuses through the pristine films at room temperature. Even though there is evidence of formation of carbonate on the surface, the samples appeared stable in the

duration of the study, except the sample with the highest lithium content which turned opaque over a few days in air.

The thickness and refractive index of the deposited films were derived from ellipsometry measurements. Both parameters correlate with the amount of pulsed lithium. There is a strong non-linear increase in thickness at high lithium pulsing ratios, probably due to the formation of lithium hydroxide which interferes with the self-limiting growth mechanism. This is also manifested in terms of increased non-uniformity for lithium rich samples. The refractive index varies quite linearly with the pulsed content of lithium, as shown in Fig. 3 and functions as a simple measure of the composition. However, high hydrogen concentrations will also contribute to a reduction in the refractive index. Hence, as long as the water dose is fairly constant, this simple approach appears as a reliable tool.

**Fig. 3** Refractive index and growth per cycle for  $\text{LiNbO}_3$  deposited using different ratios of lithium and niobium precursors.

Thickness, roughness and density information were derived from X-ray reflectometry data. It became necessary to apply a four-layer model, consisting of the substrate, native oxide of SiO<sub>2</sub>, the LiNbO<sub>3</sub>-film and a surface carbonate layer, in order to properly fit the data. The density and composition of the carbonate layer are consistent with Li<sub>2</sub>CO<sub>3</sub>. The layer is probably amorphous as it cannot be identified by diffraction experiments. The thickness of this carbonate layer increases with the amount of lithium in the film from about 5 Å at low lithium contents to about 35 Å at high contents. As expected, there is a strong correlation between lithium content and film density. The films with 73.5 and 31.3% lithium were too rough or not uniform enough to measure.

Samples of different compositions were annealed at 650 °C for 5 min in air to trigger crystallization; the annealing conditions were based on preliminary results from another study to be reported later. The corresponding diffraction patterns in Fig. 4 show that the LiNbO<sub>3</sub> phase is present in all samples with

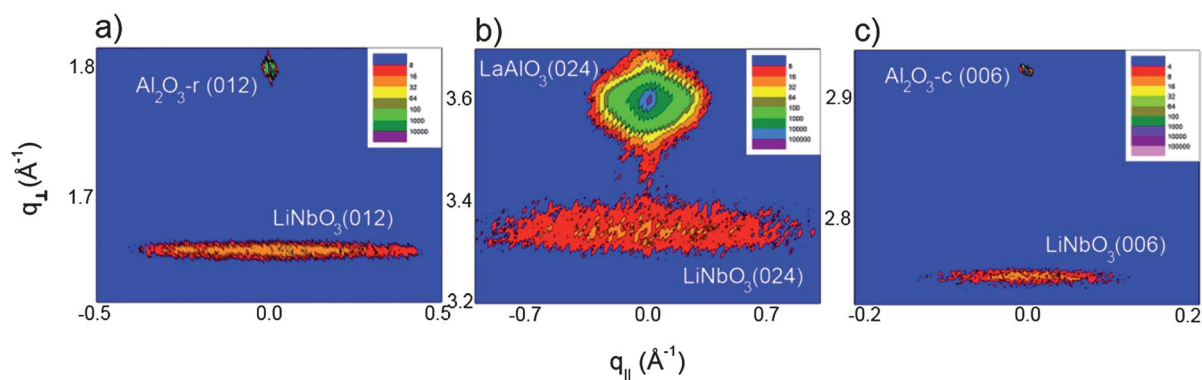

**Fig. 4** Powder X-ray diffractogram of samples with different compositions (Li pulsed content given in %) as deposited on silicon and annealed for 5 min at 650 °C. The vertical lines show positions for reflections from the LiNbO<sub>3</sub>-phase, the peak marked with \* is Si (200) and the other peaks are from Nb<sub>2</sub>O<sub>5</sub>.

a lithium to niobium pulsing ratio higher than 16%. The films deposited using 33% lithium pulses appear as phase pure according to XRD. For all cases, the samples are polycrystalline showing some preferred orientation for selected samples. For higher lithium contents, the samples remain amorphous even after annealing. The samples deposited using 33% lithium pulses (*i.e.* 666 cycles of 2Nb + 1Li) appear phase pure, although the composition as measured by TOF-ERDA is 42 ± 5.5% lithium to niobium. The excess niobium must be present as an amorphous niobium rich phase considering that the solid solubility of niobium oxide in LiNbO<sub>3</sub> is very low.<sup>37</sup>

A series of films based on 33% Li pulses were deposited on single crystal substrates and subsequently annealed in air at 650 °C for 15 min. The films were crystallized with different orientations depending on the substrates. Deposition on Al<sub>2</sub>O<sub>3</sub> (001) leads to (001) oriented LiNbO<sub>3</sub> whereas predominantly (012) oriented films were obtained on LaAlO<sub>3</sub> (012) and Al<sub>2</sub>O<sub>3</sub> (012), as shown in Fig. 5 and 6. Deposition on SrTiO<sub>3</sub> (001) resulted in a mixture of (012) and (001) oriented crystallites. It is surprising that the film does not orient well on SrTiO<sub>3</sub> as it is known that LaAlO<sub>3</sub>, which is different from LiNbO<sub>3</sub> only by an inversion centre, grows epitaxially oriented as SrTiO<sub>3</sub> (100)|SrTiO<sub>3</sub>[100]||LaAlO<sub>3</sub> (012)|LaAlO<sub>3</sub>[100] when deposited with ALD.<sup>38</sup> A more detailed reciprocal space mapping was then performed on the Al<sub>2</sub>O<sub>3</sub> and LaAlO<sub>3</sub> substrates which revealed quite large in-plane peak broadening compared to the out-of-plane broadening, see Fig. 5. Rocking curve analysis showed that *c*-Al<sub>2</sub>O<sub>3</sub>, *r*-Al<sub>2</sub>O<sub>3</sub> and LaAlO<sub>3</sub> had peak broadening of the first symmetric reflection (006 or 012) of 1.05°, 2.04° and 1.76°, respectively. In order to reveal the full epitaxial relationship on the different substrates reciprocal space maps and  $\phi$ -scans were performed.

$\phi$ -Scans were performed on the (10.10)-reflection of the sample deposited on *c*-Al<sub>2</sub>O<sub>3</sub> or the (122)-reflection of LaAlO<sub>3</sub> or *r*-Al<sub>2</sub>O<sub>3</sub> and the  $\phi$ -scans revealed a perfect epitaxial relationship as shown in Fig. 8 and the ESI.† It was difficult to obtain reciprocal space maps of asymmetric reflections suitable for determination of the epitaxial relationship between the substrate and the film, both considering the intensity and geometrical constraints. An asymmetric reflex, (122), for *r*-cut

**Fig. 5** Reciprocal space maps of symmetric reflections for (a) LiNbO<sub>3</sub> (012) on *r*-cut sapphire, (b) LiNbO<sub>3</sub> (024) on LAO and (c) LiNbO<sub>3</sub> (006) on *c*-cut sapphire. All show the proof of ordering identical to the substrate cut. The relatively large broadening in  $q_{\parallel}$  is attributed to a small random tilt of the normal axis. Note, however, the very delimited tilt along the symmetric axis.

**Fig. 6** X-ray diffractogram collected in  $\theta$ - $2\theta$  mode of a film deposited using 666 super-cycles consisting of two cycles of  $\text{Nb}(\text{OEt})_5$  and  $\text{H}_2\text{O}$  and one cycle of  $\text{LiN}(\text{SiMe}_3)_2$  and  $\text{H}_2\text{O}$ , thereafter annealed for 15 min at  $650^\circ\text{C}$ . The substrates were  $\text{Al}_2\text{O}_3$  (001),  $\text{LaAlO}_3$  (012),  $\text{Al}_2\text{O}_3$  (012) and  $\text{SrTiO}_3$  (001). The substrate peaks are labelled with \*.

**Fig. 7** Reciprocal space map of the asymmetric (122)-reflection in the  $\text{Al}_2\text{O}_3$  r-cut||LNO-system. The delimited intensity points towards an in-plane ordering in addition to the already described normal ordering.

$\text{Al}_2\text{O}_3$  (normal axis: (012)) was collected, showing the delimited intensity at the expected  $q$ -values for  $\text{LiNbO}_3$  (122), Fig. 7.

The observed ordering both in-plane and normal to the film, as measured on the r-cut sapphire substrate, points towards a strict epitaxial relationship on annealed substrate||film-

**Fig. 8**  $\phi$ -Scan of the (122)-reflection for a film deposited on  $\text{LaAlO}_3$ , proving the epitaxial relationship described.

systems, represented by  $\text{Al}_2\text{O}_3$  (012)|| $\text{Al}_2\text{O}_3$ [100]|| $\text{LiNbO}_3$  (012)|| $\text{LiNbO}_3$ [100]. An equivalent relationship is also shown for films deposited on  $\text{LaAlO}_3$ .

For c- $\text{Al}_2\text{O}_3$  the relationship is  $\text{Al}_2\text{O}_3$  (001)|| $\text{Al}_2\text{O}_3$ [100]|| $\text{LiNbO}_3$  (001)|| $\text{LiNbO}_3$ [100] where the polar  $c$ -axis is oriented normal to the film. The surface morphology was characterised by AFM, see representative sample regions for different substrates in Fig. 9 and consists of crystallites with 200–300 nm diameter, separated by grain boundaries with precipitates of smaller crystallites. The crystallite size normal to the surface is estimated to be  $44 \pm 10$  nm using a simplified Williamson–Hall approach based on the FWHM broadening of symmetric diffraction peaks of epitaxial films. The deviation in the TOF-ERDA compositional ratio of 1 : 1 for the lithium to niobium content, see above, indicates that the precipitates along the grain boundaries represent a nano-crystalline or amorphous niobium rich phase, possibly  $\text{LiNb}_3\text{O}_8$  or niobium pentoxide. The RMS-roughness of the  $\text{LiNbO}_3$  films deposited on silicon,  $\text{Al}_2\text{O}_3$  (001),  $\text{Al}_2\text{O}_3$  (012), and  $\text{LaAlO}_3$  (012) are 1.6, 1.3, 1.3, and 1.8 nm, respectively. The roughness of the individual  $\text{LiNbO}_3$  facet surfaces is in the order of 0.1 nm.

The diffraction patterns in Fig. 6 suggest that the films deposited on different substrates should yield different morphologies as the exposed crystal facets are different. AFM images collected of the different samples show that this is indeed the case, as shown in Fig. 9. The sample deposited on Si (100) shows large grains with almost atomically flat plateaus, but no apparent crystal facets. However, the epitaxially oriented films show clearly crystallite shapes. On  $\text{Al}_2\text{O}_3$  (001) the dominant crystallite shapes are triangular, reflecting the three-fold rotation axis normal to the surface. Furthermore, on  $\text{Al}_2\text{O}_3$  (012) and  $\text{LaAlO}_3$  (012), the crystallites take octahedral morphology with flat tops, reflecting the symmetry in the (012) plane of the  $\text{Al}_2\text{O}_3$ ,  $\text{LiNbO}_3$ , and  $\text{LaAlO}_3$  crystal structures.

The piezoelectric response of a  $\text{LiNbO}_3$  thin film on silicon was studied using a PFM-setup where an external alternating current bias is applied to the tip. The piezoelectric response from the ferroelectric thin film created a modulated deflection

**Fig. 9** AFM images of films deposited on (a) Si (100), (b) Al<sub>2</sub>O<sub>3</sub> (001), (c) Al<sub>2</sub>O<sub>3</sub> (012) and (d) LaAlO<sub>3</sub> (012) using 666 super-cycles each consisting of two cycles of Nb(OEt)<sub>5</sub> and H<sub>2</sub>O and one cycle of LiN(SiMe<sub>3</sub>)<sub>2</sub> and H<sub>2</sub>O, thereafter annealed for 15 min at 650 °C.

**Fig. 10** Left:  $1.5 \times 1.5 \mu\text{m}^2$  C-AFM topography image. Right: the same area scanned using piezoelectric force microscopy, showing the piezoelectric domain structure of a LiNbO<sub>3</sub> thin film deposited on a silicon substrate using 666 super-cycles each consisting of two cycles of Nb(OEt)<sub>5</sub> and H<sub>2</sub>O and one cycle of LiN(SiMe<sub>3</sub>)<sub>2</sub> and H<sub>2</sub>O, thereafter annealed for 15 min at 650 °C. The back contacts were made of silver paint.

of the PFM-tip, which was extracted using an external lock-in amplifier. In Fig. 10 such responses are clearly observable as separate regions with an 180° phase deviation that reflects the relative alignment of the polar axis. The sizes of the domains are similar to those of the crystalline grains. A ferroelectric behaviour of the samples was confirmed by hysteresis loop measurements, Fig. 11. The observed remanent polarization is

**Fig. 11** Measured ferroelectric hysteresis loop measured at 1 kHz for a 120 nm thick LiNbO<sub>3</sub> film on a silicon substrate with electrical contacts made from silver paint.

$0.4 \mu\text{C cm}^{-2}$  and the coercive field is approximately  $220 \text{ kV cm}^{-1}$ . This is consistent with previous experimental values of around  $200 \text{ kV cm}^{-1}$  for bulk LiNbO<sub>3</sub>, and significantly higher than the value of  $130 \text{ kV cm}^{-1}$  previously measured for LiNbO<sub>3</sub> thin films on silicon.<sup>14,39–41</sup>

## Discussion

In order to reproducibly achieve the targeted LiNbO<sub>3</sub> films it was proved necessary to always deposit 2000 cycles of Nb<sub>2</sub>O<sub>5</sub> between each deposition with high lithium content. Several attempts were made to reproduce the sample closest to the stoichiometric composition after the following scheme: (a) verify the growth of Nb<sub>2</sub>O<sub>5</sub>, (b) test LiNbO<sub>3</sub> deposition and (c) deposit LiNbO<sub>3</sub> on single crystal substrates. Parts (a) and (b) always worked while (c) always failed, meaning that it proved impossible to deposit two successive deposition of LiNbO<sub>3</sub> after breaking the vacuum. No detailed analysis was made of the failed runs, yet ellipsometry measurements yielded too high refractive index compared to the one previously obtained for the stoichiometric phase, and XRD shows niobium rich phases of Nb<sub>2</sub>O<sub>5</sub> and LiNb<sub>3</sub>O<sub>8</sub>. Even if the stoichiometry was not reproduced, the films were still uniform and no powders were formed. Experiments with alternating deposition of LiNbO<sub>3</sub> and Nb<sub>2</sub>O<sub>5</sub> were always successful, and this was then adopted as the standard protocol. We note that deviation from the expected stoichiometry always resulted in more niobium rich samples, which were uniform, with no powder formation and in the expected thickness range. One may speculate whether a likely mechanism is that the lithium containing material absorbs water during the water pulse and releases water during the metal pulse, through the so-called reservoir effect, a similar case was recently found by Comstock and Elam when studying the reaction mechanisms of Li–Al–O deposition.<sup>42</sup> Why this shifts the stoichiometry towards the niobium rich side requires further investigations.

The surface layer of the LiNbO<sub>3</sub> samples is dominated by Li<sub>2</sub>CO<sub>3</sub> which is consistent with an observed enrichment of lithium on the surface. The depth profiles from TOF-ERDA show that the lithium to niobium ratio is constant throughout the film, except on the very surface. This suggests that lithium ions are mobile and diffuse even at room temperature, ruled by the chemical potentials of CO<sub>2</sub> and H<sub>2</sub>O in ambient air. Our

hypothesis is that an excess of lithium species on the surface is the origin of uncontrolled growth, based on the observations so far. The excess lithium on the surface of the chamber may either be caused by consecutive lithium cycles or by Li-diffusion throughout the deposited film when exposed to ambient air. This behaviour may also be transferrable to other deposition processes of lithium compounds by ALD.

The LiNbO<sub>3</sub> films have a strong tendency to order epitaxially on substrates such as LaAlO<sub>3</sub> and Al<sub>2</sub>O<sub>3</sub>. Epitaxial ordering is expected as the structures are similar and the lattice mismatch is 1.2 and 3.9% for LaAlO<sub>3</sub> and r-Al<sub>2</sub>O<sub>3</sub> respectively, when assuming pseudocubic unit cells with cell parameters of 3.79 and 3.48 Å, respectively, when compared to 3.76 Å for LiNbO<sub>3</sub>. On the structurally very similar Al<sub>2</sub>O<sub>3</sub> and LaAlO<sub>3</sub>, the orientation of the thin film is selective as shown in Fig. 5–8. The lack of observed selective ordering on SrTiO<sub>3</sub> is believed to stem from a difference in octahedral tilt, as SrTiO<sub>3</sub> has no octahedral tilt (SG Pm-3m), compared to a (a<sup>-</sup>, a<sup>-</sup>, a<sup>-</sup>)-tilt in LaAlO<sub>3</sub> and a stronger tilt of the same type in LiNbO<sub>3</sub>. In any case, depending on the substrate, control of orientation is achieved. LaAlO<sub>3</sub> does order on SrTiO<sub>3</sub> but even though the type of tilt is similar to LiNbO<sub>3</sub>, the amount of tilt is very large in LiNbO<sub>3</sub> compared to LaAlO<sub>3</sub>.

The coercive field for the LiNbO<sub>3</sub> thin films is around 220 kV cm<sup>-1</sup>. This is comparable to earlier reported values for congruent LiNbO<sub>3</sub>. The ferroelectric domains are pure and domain walls are well defined as shown by PFM-measurements. It is likely that the coercive field can be engineered by varying the stoichiometry of the LiNbO<sub>3</sub> thin films, which would open up for tailoring features for a range of applications.

## Conclusion

Epitaxial thin films of ferroelectric LiNbO<sub>3</sub> have been deposited with ALD. The films have been analyzed using X-ray- and ion-scattering techniques, ellipsometry, and scanning probe microscopy as well as by ferroelectric characterization. Fundamental issues connected with deposition of lithium containing oxides have been identified and discussed, especially possible limitations in the lithium content and room temperature diffusion of lithium.
