I. Introduction

Platinum group metal (PGMs) and gold nanoparticles (NPs) are promising heterogeneous catalysts for the selective aerobic oxidation (selox) of alcohols to aldehydes, providing routes that obviate the use of environmentally harmful inorganic oxidants (e.g. Cr(VI) salts or permanganates) and their associated toxic waste, handling of hazardous peroxides, or the recovery of solvent,3 handling of hazardous peroxides, or the recovery of precious organometallic soluble catalysts. Recent research has highlighted Au, Pd5,6 and bimetallic nanoparticles thereof7–10 as atom-efficient selox catalysts, able to operate under mild conditions (e.g. reaction temperatures between 60–160 °C and employing ambient air as an oxidant) in non-halogenated solvents, aqueous solutions11 or even solventless.7 The active site in oxide supported Pd NPs for crotyl alcohol selox has been extensively investigated by in situ and operando X-ray spectroscopies.12–15 These reveal that oxygen is critical in weakening the adsorption of the reactively-formed crotonaldehyde product thereby reducing decarbonylation pathways. We have made similar observations over Pd(111)16 and Au/Pd(111)9,17 model single-crystal catalysts, wherein in situ XPS and TPRS measurements show that pre-adsorbed oxygen weakens crotonaldehyde adsorption over pure palladium and Au/Pd surface alloys, thus suppressing undesired decarbonylation pathways. This contrasts with epoxidation wherein oxygen promotes ethene adsorption over silver.18 Enhanced activity of Au/Pd core shell nanoparticles in crotyl alcohol selox has been rationalized by d-charge depletion observed via XANES measurements.10

Chin et al. recently explored the influence of co-adsorbed oxygen on methane combustion over Pd and Pt NPs,19,20 while ethanol selective oxidation to ethanol was studied over Au NPs via DFT calculations by Boronat and Corma,21 who found that oxygen lowered the activation barriers for O–H and C–H scission. Delbecq and Sautet also employed DFT in combination with HREELS22 vibrational measurements to study crotonaldehyde
adsorption over Pt(111)\textsuperscript{22} and Pt$_2$Sn/Pt(111)\textsuperscript{24} alloys, and thereby understand the influence of Sn additives on catalyst selectivity towards the hydrogenation of crotonaldehyde and other $\nu$-$\beta$-unsaturated aldehydes. DFT has also been applied in conjunction with metastable de-excitation spectroscopy to elucidate the molecular adsorption modes and reaction pathways during crotyl alcohol selox over bare Pd(111).\textsuperscript{25}

In this contribution, the effect of co-adsorbed oxygen on the adsorption of crotonaldehyde is explored for the first time via DFT calculations. In particular, we provide fundamental insight into the impact of co-adsorbed oxygen upon crotonaldehyde adsorption over Au NPs, and discuss the resulting implications for crotyl alcohol selox. We present a systematic computational study of crotonaldehyde adsorption over gold NPs (diameter, $d < 1$ nm) as a function of co-adsorbed oxygen surface coverage and proximity. The configurational space for adsorbed crotonaldehyde on bare Au$_{13}$ and Au$_{18}$ NPs and their oxidised analogues (Au$_{13}$O$_n$, $n = 2$, 4, 6 and 8 and Au$_{18}$O$_2$) at effective oxygen coverages between 0–1 monolayers has been explored, and associated adsorption energies calculated. For low oxygen coverage on Au$_{13}$ particles we find that crotonaldehyde adsorption can be enhanced relative to the bare Au cluster. However, strong destabilisation of crotonaldehyde by co-adsorbed oxygen is found at full oxygen coverage because adsorbed oxygen adatoms occupy positions close to the molecular adsorption site. The concepts discussed are likely extendable to other PGM NPs, and suggest that controlling oxygen surface coverage in situ may aid process optimization during the catalytic selox of allylic alcohols.

II. Methods

\Gamma$ point\textsuperscript{26} DFT calculations were performed with the VASP 5.2 code.\textsuperscript{27,28} Exchange and correlation effects are considered within the generalized gradient approximation (GGA) using the Perdew–Burke–Ernzerhof (PBE) exchange–correlation (XC) functional,\textsuperscript{29} with the projector augmented-wave (PAW) method\textsuperscript{30,31} used to represent core states, 1s for C and O, and 1s to 4f for Au. The cut-off energy for the plane-wave basis was set to 400 eV. The nanoparticle/adsorbate models were centered within a $25 \times 25 \times 25$ Å periodic box to ensure a vacuum gap of 15–20 Å around the clusters, with most calculated results obtained at the latter gap. Geometry optimizations of all the atoms in the cluster–adsorbate system were performed with a residual force threshold of 0.015 eV Å$^{-1}$ using the conjugate-gradient algorithm. The convergence criterion for electronic relaxation was 10$^{-4}$ eV. The initial charge density was obtained by superposition of atomic charges, and the projection operators were evaluated in reciprocal space. Spin polarization has been tested in several models but found to be unimportant, with calculated adsorption energies agreeing to within 0.5 kJ mol$^{-1}$ for calculations with and without spin polarisation.

Molecular gas phase optimizations were also performed with the Gaussian09 code (rev C.01)\textsuperscript{32} to allow comparison of results with the Becke’s three-parameter, hybrid exchange functional\textsuperscript{33} combined with the Lee–Yang–Parr non-local correlation functional,\textsuperscript{34} abbreviated as B3LYP, using the aug-cc-pVTZ\textsuperscript{35} basis set. Linear dependencies of the basis functions were removed by using the spherical version (5d, 7f) of the aug-cc-pVTZ basis set.

Adsorption energies ($E_{\text{ads}}$) were calculated by subtracting the total energy of the fully-relaxed, isolated adsorbate and nanoparticle from the total energy of the adsorbate-nanoparticle system.

The degree of adsorption-induced charge transfer was estimated through the atomic charges calculated by Bader’s atoms-in-molecules method using the numerical grid based approach developed by Henkelman and co-workers.\textsuperscript{36,37} These authors have noted that the convergence of Bader charges requires the charge density to be produced on a fine grid so that the spacing between grid points is of the order of 0.02 Å.\textsuperscript{37} VASP works with two grids to represent the charge density, and outputs the finer grid for analysis. The memory requirement for such calculations on the 25 Å cube used to isolate the clusters within the periodic boundary conditions of the simulation was prohibitive on our resources. Accordingly, charge analysis was carried out for each system within a 16 Å cubic simulation cell using the structures optimized within the larger cell. This allowed us to produce a grid with 700 points on a side corresponding to a grid spacing of 0.023 Å. As a check on the numerical accuracy of the analysis we carried out additional calculations for ethene adsorbed in a di-σ fashion to the Au$_{13}$ cluster. In this case Bader analysis gave C atom charges of $-0.1664$ [e] and $-0.1640$ [e]. Since the carbon atoms for ethene should be equivalent by symmetry we infer a numerical accuracy of 0.005 [e]. Accordingly, Bader charges are quoted to two decimal places throughout the manuscript. These ethene calculations help inform on C–C double bond interactions with the various clusters studied, and provide an additional reference point for discussing the crotonaldehyde results.

III. Results and discussion

The rotational isomers of free crotonaldehyde were first optimized to determine the lowest energy gas phase conformers. We found four local minima on the potential energy surface, denoted as $E(\text{s})$-trans, $E(\text{cis})$-cis, $Z(\text{s})$-trans and $Z(\text{cis})$-cis as depicted in Fig. 1a–d. The heavy atom molecular framework of all rotamers was found to be planar, indicative of π-conjugation of the C=C and C=O moieties. As expected for rotational isomers, there is a negligible change of the corresponding bond lengths between the various isomers. The ordering of the relative energies for the four rotamers was found to be $E(\text{s})$-trans $< E(\text{cis})$ $< Z(\text{s})$-trans $< Z(\text{cis})$ (0.0 kJ mol$^{-1}$). Of the four rotational isomers identified, $E(\text{s})$-trans crotonaldehyde was the most stable in the gas phase, in agreement with microwave spectroscopy experiments\textsuperscript{38} on crotonaldehyde. It is noteworthy that this energy trend is found for both plane-wave and atom-centered basis (i.e. B3LYP/aug-cc-pVTZ) methodologies. Subsequently we have used $E(\text{s})$-trans to evaluate the effect of co-adsorbed oxygen on the adsorption strength of the desirable product in the selective oxidation of crotyl alcohol, although the general conclusions that follow have also been validated for the second lowest energy conformer ($E(\text{cis})$).
For the gold nanoparticle two particle sizes have been used, Au$_{13}$ and Au$_{38}$. In each case the structures were taken from bulk gold ($a = \beta = \gamma = 90^\circ$, $a = b = c = 407.82$ pm) and fully optimized to their nearest energetic minima. Both Au$_{13}$ and Au$_{38}$ NPs expose (100)-like and (111)-like facets which are also found on gold NPs of different geometries. Au$_{38}$ has previously been described as an efficient catalyst for molecular oxygen dissociation with DFT calculation results being confirmed experimentally. After adsorption of molecular oxygen on a (100) facet a low barrier was calculated to produce O-adatoms in 3-fold hollow sites (h-O) on adjacent (111) sections of the particle. In Fig. 2 we consider the energetics of h-O adsorption on an Au$_{13}$ cluster by plotting the relative energy of the oxidised cluster compared to Au$_{13}$ and the corresponding number of gas phase O$_2$ molecules as a function of oxygen coverage. Successive addition of oxygen adatoms thermodynamically stabilizes this system due to the formation of linear O–Au–O structures, which have been previously reported during O$_2$ dissociation on gold clusters and employed as an indicator of gold oxide formation. In particular, we find the relative energy calculated for oxidised Au$_{13}$ is linearly dependent on the oxygen coverage. This suggests that in an oxidising atmosphere the Au nanoparticles considered here will become surface oxidised.

We note that DFT in general suggests that small isolated clusters of bare gold (e.g. Au$_4$, Au$_{12}$) preferentially adopt a planar structure, whereas larger Au$_n$ clusters ($n > 13$) favour 3D morphologies that introduce low-coordination edge and vertex sites alongside (100) facets. However, for surface supported nanoparticles, three-dimensional morphologies are observed even for small particles. In the present context we note that oxidation of nanoparticles leads to linear O–Au–O structures as Au atoms are oxidized, and that these will for thermodynamic reasons more easily be accommodated within three dimensional structures. Accordingly, our use of bulk like structures allows the comparison of crotonaldehyde adsorption as a function of cluster size and oxygen coverage using a consistent cluster geometry which is also in line with the shapes of the supported Au nano-particles used in selox experimentally.

In the subsequent section we explore the various adsorbed configurations of E-(s)-trans-crotonaldehyde on nanometer scale Au particles and examine the effect of co-adsorbed oxygen and cluster size on the adsorption energetics. The four lowest energy bound structures for each cluster studied are given in Fig. 3. For the bare Au$_{13}$ cluster (Fig. 3a) the most favourable adsorption geometry is $\sigma_{CC}$ which is some 15 kJ mol$^{-1}$ lower in energy than the atop and di-$\sigma_{CC}$ modes. The di-$\sigma_{CC}$ structures

![Fig. 1](structure_and_nomenclature_of_rotational_isomers_of_crotonaldehyde_obtained_at_E_cut=400_eV_in_a_25x25x25_A_periodic_cubic_cell_all_bond_lengths_given_in_A_.png)

![Fig. 2](relative_total_energy_of_Au_{13}O_{n},_where_n=0,2,4,6_and_8_for_the_various_possible_permutations_of_three-fold_hollow_oxygen_the_least_squares_line_is_drawn_for_minimum_energy_structure_at_each_oxygen_coverage.png)

![Fig. 3](adsorption_energies_of_di-\sigma_{CC}, \sigma_{CC} and atop-bonded_conformations_of_E-(s)-trans-crotonaldehyde_on_neutral_a_Au_{13},_b_Au_{13}(h-O)_8,_c_Au_{38} and_d_Au_{38}(h-O)_2.png)
are akin to ethylene adsorption on neutral, anionic and cationic gold clusters.49 For E(s)-trans crotonaldehyde adsorption to the clusters we distinguish two di-σcc geometries; in di-σcc-1 the aldehyde group is toward an Au–Au bridge site while for di-σcc-2 it is orientated away from the cluster. For Au13 and Au18 (Fig. 3c) these two alternatives are practically isoenergetic. However, for the oxidized clusters (Au13(h-O)8, Fig. 3b and Au18(h-O)2, Fig. 3d), locating the aldehyde over the bridge site places this group near an h-O atom, which is more destabilizing than locating the methyl group in the same position such that di-σcc-2 becomes notably lower in energy than di-σcc-1.

Delbecq and Sautet have provided a survey of adsorption configurations for acrolein (propenal) and crotonaldehyde on Pt(111),23,24 along with calculated adsorption energies using the PW91 functional. For the E(s)-trans isomer they considered five adsorption modes. Two of these adsorb via the C=C bond; di-σcc for which C=C interacts with two surface Pt atoms and πcc which involves only a single Pt atom. Adsorption via the C=O moiety gives a further two possibilities; di-σcc and atop with the molecule adsorbed in an end-on fashion through a Pt...O=C interaction. Finally, a η1 configuration was examined involving both C=C and C=O bonding to separate Pt atoms. For crotonaldehyde this latter η1 adsorption geometry gave the lowest calculated adsorption energy (−84.5 kJ mol−1).

The adsorption configurations we have located are in general agreement with the earlier work on Pt. Interestingly, the η1 structure for adsorbed E(s)-trans crotonaldehyde previously shown to have the potential to undergo decarbonylation over Pd(111)25 was not found on Au13O8. This implies that oxidised sub-nanometer Au NPs may afford higher crotonaldehyde selectivity rather than decarbonylation, during crotyl alcohol to crotonaldehyde selox. For the remaining configurations, we find that adsorption through the C=C bond and C=O moieties are possible on both Au13 and Au18 clusters. The NP structure gives rise to edge and corner sites where the facets meet and these are found to be preferred over adsorption on the facets themselves. For Au13 structures bound through the C=C moiety generally adsorb more strongly than those via oxygen bound atop (Fig. 3a). However, in the presence of co-adsorbed oxygen we find that atop adsorption actually becomes more favourable (Fig. 3b). Side reactions that could potentially lead to attack at the allylic bond in the C=C bound configurations di-σcc-1, di-σcc-2 and πcc are thus less probable for oxidized sub-nanometer Au NPs because atop adsorption through the aldehyde oxygen atom is energetically favoured. For Au18 this preference is less clear as the different adsorption modes shown in Fig. 3c fall within a narrow range (3.6 kJ mol−1). We have also examined the adsorption energy of di-σ and π-bound E(s)-trans crotonaldehyde on Au(111) (see ESI† Fig. S1) and found that the adsorption energy is essentially zero (1.1 kJ mol−1) indicative that on extended gold surfaces crotonaldehyde can only weakly interact. Comparing the lowest adsorption energies for Pt(111),23,24 Au NPs and Au(111) yields the following trend for crotonaldehyde: Pt(111) (η1: −85 kJ mol−1) > Au13 (πcc: −71 kJ mol−1) > Au18 (atop, di-σcc-1 or di-σcc-2: −47 kJ mol−1) > Au18(h-O)2 (πcc: −34 kJ mol−1) > Au13(h-O)8 (atop: −28 kJ mol−1) > Au(111) (1.1 kJ mol−1).

It is remarkable that the smaller Au cluster gives an adsorption energy just 14 kJ mol−1 less negative than the Pt(111) value. In contrast, the Au18 value is 38 kJ mol−1 less favourable than Pt(111) whereas on Au(111) there is practically no interaction at the PBE-level, revealing a strong particle size dependence of the adsorption energy. This weakened adsorption would imply a pronounced particle size-sensitivity for allylic alcohol selox over gold NPs, with the desired crotonaldehyde product preferentially destabilized over larger particles or small NPs that are oxidised (i.e. Au13O8). It is also apparent from Fig. 3 that the energy differences between adsorption to the different sites on a particle fall into a much narrower range for Au18 (3.1 kJ mol−1) than for Au13 (15.3 kJ mol−1).

Co-adsorbed oxygen exerts an even greater influence on crotonaldehyde adsorption energetics than does particle size. Specifically, we observe a 94%, 86%, 71% and 51% decrease in the magnitude of adsorption energies for E(s)-trans in the di-σcc-1, di-σcc-2, πcc and atop geometries respectively when Au13 NPs are pre-saturated with oxygen adatoms; this equates to an average decrease of 45 kJ mol−1 upon nanoparticle oxidation.

In later sections we will show that for Au13 the weakening of adsorption observed for the di-σcc geometries on the fully oxidised cluster, Au13(h-O)8, occurs due to the proximity of a h-O atom at the position closest to the bridge site where the molecule is placed (see asterisk in Fig. 3a). A similar arrangement was constructed for the partially oxidized Au18(h-O)2 cluster, however, attempts to locate an oxygen atom in the 3-fold hollow site neighboring the C=C bond destabilized E(s)-trans crotonaldehyde to such an extent that no optimized adsorption geometry could be found. Interestingly we find that if we place an oxygen at the neighbouring 3-fold hollow and keep di-σ-bound crotonaldehyde at a fixed position, then oxygen diffusion to the adjacent (111)-like facet is observed. However, for Au18(h-O)2, the presence of oxygen adatoms at other adjacent sites also decreased the magnitude of crotonaldehyde adsorption by between 10–45 kJ mol−1 (compare Fig. 3c and d). Such findings provide evidence for a strong oxygen-induced destabilization of allylic aldehyde adsorption over gold nanoparticles. The origin of this dramatic destabilization, and its oxygen coverage dependence, reflects an intriguing and complex bonding mechanism that we explore in the following sections.

Boronat and Corma have shown that molecular O2 adsorption on the (100) facets of Au13 clusters can yield h-O adatoms on neighbouring (111) facets. We have used the idea of oxygen dissociation on (100) leading to h-O on opposing (111) facets to build-up the oxygen adatom population on an Au13 cluster and examined the effect upon E(s)-trans crotonaldehyde adsorption in the di-σcc-2 and πcc configurations. The dependence of crotonaldehyde adsorption over Au13 on co-adsorbed oxygen coverage is shown in Fig. 4. In Fig. 4, each structure has an O atom placed in the hollow site closest to the adsorbate; this clearly has a dramatic effect on the calculated adsorption energy even at low coverage. Indeed for the di-σcc configuration, dissociation of a single oxygen molecule into such an arrangement leads to 53.1 kJ mol−1 fall in
the crotonaldehyde adsorption energy; for intermediate coverages, progressive addition of further oxygen adatoms slightly enhances adsorption with calculated energies increasing from $-2.1$ (Au$_{13}$(h-O)$_{2}$) to $-16.5$ kJ mol$^{-1}$ (Au$_{13}$(h-O)$_{6}$).

At full coverage (Au$_{13}$(h-O)$_{8}$) adsorption weakens again, being destabilized by 47.2 kJ mol$^{-1}$ with respect to the bare Au$_{13}$ cluster. A very similar trend is also observed for the $\pi_{CC}$ configuration, where on average the adsorption energies are 11 kJ mol$^{-1}$ stronger than for the di-$\sigma_{CC}$ configuration (excluding Au$_{13}$O$_{2}$). For this crotonaldehyde adsorption geometry over Au$_{13}$O$_{2}$, the adjacent h-O shifts away from the aldehyde to a two-fold bridged oxygen (b-O) position, relieving the steric interaction.

Fig. 4 highlights the impact of h-O oxygen atoms located in the (111)-like adsorption site neighboring an adsorbed crotonaldehyde molecule. Such proximate adsorption to the C=C bond dramatically reduces the strength of crotonaldehyde adsorption. However, there are clearly other sites available for all intermediate oxygen coverage levels, which are only lost at the point of hollow site saturation (Au$_{13}$(h-O)$_{6}$). Fig. 5 explores the effect of h-O oxygen atom placement on the adsorption of E-(s)-trans crotonaldehyde in the di-$\sigma_{CC}$-2 geometry over Au$_{13}$(h-O)$_{6}$.

The results fall into two broad categories. When the proximal h-O site is occupied, crotonaldehyde adsorption is destabilized (as reported in Fig. 4). Fig. 5 reveals that the oxygen atom arrangement in Fig. 4 actually represents one of the more strongly bound examples of such structures, with crotonaldehyde adsorption varying between $+0.8$ and $-16.5$ kJ mol$^{-1}$. Locating an oxygen adatom in the (111)-like hollow site nearest to the adsorbed molecule weakens crotonaldehyde binding by an average of 59 kJ mol$^{-1}$. By comparison, when the proximal h-O site is unoccupied, crotonaldehyde adsorption is enhanced by between 5.5 and 13.6 kJ mol$^{-1}$ relative to the bare Au$_{13}$ cluster. This finding has clear implications for practical catalysis, since occupancy of the proximal h-O site can only be guaranteed at saturation oxygen adatom surface coverages, with high binding energy sites for strong crotonaldehyde adsorption available on partially oxidized gold NPs. High oxygen partial pressures/dissolved concentrations should thus eliminate reaction pathways involving crotonaldehyde adsorption at strongly adsorbing sites which likely favour decarbonylation versus desired competing desorption pathways. Fully oxidized gold NP catalysts are anticipated to disfavour the adsorption of related allylic aldehydes with respect to their naked gold counterparts, and may also interact more weakly with other unsaturated organic molecules that typically coordinate through C=C functions.

Of the two clusters explored in the present work, Au$_{13}$ is unique in that each (111) like facets contains only a single three-fold hollow site. Larger clusters possess extended facets, so that even on Au$_{13}$ each (111) face contains six hollow sites. Occupancy of all such (111) hollow sites by oxygen adatoms is unlikely since this would place h-O atoms close to one another. Boronat and Corma$^{21}$ suggest that a Au$_{13}$O$_{16}$ cluster, in which only a third of the available h-O sites are occupied, represents a saturated oxide monolayer. In this latter scenario, crotonaldehyde adsorption could away from a neighboring h-O atom. It is noteworthy from Fig. 3 that such open adsorption sites on larger clusters would still be destabilized with respect to the bare cluster by 9.7 kJ mol$^{-1}$ ($\pi_{CC}$) and 44.4 kJ mol$^{-1}$ (di-$\sigma_{CC}$-1). Hence, nanometre gold nanoparticles partially oxygen covered remain able to absorb crotonaldehyde with moderate energies ($-20$ to $-40$ kJ mol$^{-1}$) at sites that are not directly adjacent to oxygen adatoms.

Fig. 5 reveals that oxygen adsorption over for Au$_{13}$ can either enhance or destabilize crotonaldehyde adsorption, and we now advance a bonding model to explain these observations. The di-$\sigma_{CC}$ mode of bonding can be viewed in terms of donation from the C=C $\pi$-density to empty metal orbitals, and back donation from the filled metal d-states into the anti-bonding $\pi^*$-orbitals of the allylic bond. These combined effects change the structures of C=C double bonds as the carbon atoms alter from sp$^2$ toward sp$^3$ geometries. The structural analyses presented in Fig. 6 for crotonaldehyde over bare and oxidized Au$_{13}$ NPs reveal qualitative trends in line with this model. We find generally shorter di-$\sigma_{CC}$ bond lengths ($r_{Au-C}$) for the more strongly adsorbed configurations (Fig. 6a) accompanied by a decreased dihedral angle $\varphi_{H-C_{2}-C_{3}-H}$ for crotonaldehyde, indicative of sp$^3$ to sp$^3$ rehybridization of the two C atoms in the olefinic bond. For metals with a filled d-shell such as Au, we would also expect the interaction with the bare cluster to be dominated by metal to adsorbate back donation.

The sub-set of structures lacking an h-O atom adjacent to crotonaldehyde exhibit stronger di-$\sigma_{CC}$-2 adsorption than occurs on the bare Au$_{13}$ cluster (Fig. 5). These structures have correspondingly shorter $r_{Au-C}$ bonds by $\sim 0.043$ Å, and smaller $\varphi_{H-C_{2}-C_{3}-H}$ dihedral angles (142° versus 147°) than for the bare cluster, consistent with strong rehybridization of the two C atoms in the C=C moiety in the presence of h-O adatoms. This likely reflects oxidation of the Au atoms to which the crotonaldehyde is bound; cationic gold, having a smaller effective radius than the neutral atom species, permits closer approach of the adsorbate, while the associated depopulation of d-states facilitates adsorbate to cluster charge donation in concert with
the metal to adsorbate back donation that also operates on the bare cluster. The two Au atoms coordinating to crotonaldehyde are also 0.046 Å closer in this set of oxidized clusters than they are for the parent Au$_{13}$ cluster, probably reflecting distortion of the former arising from the stronger C=O binding.

A similar picture emerges for the sub-set of structures in which the three-fold hollow site closest to crotonaldehyde is occupied by oxygen, for which aldehyde adsorption is significantly weaker than on bare Au$_{13}$. These configurations have generally longer $r_{Au-C}$ bonds (spanning 2.156 Å to 2.222 Å) and $\phi_{H-C2-C3-H}$ dihedral angles closer to the 180° value expected for the planar C=O double bond in the unbound aldehyde. Although the two coordinating Au atoms in this sub-set are again expected to be electron deficient due to adsorbed oxygen, the attractive interactions from molecule-to-metal electron donation have to be balanced against the steric repulsion between crotonaldehyde and the proximate h-O oxygen atom. Fig. 6c shows that oxygen adatoms placed near crotonaldehyde significantly increase the separation of Au atoms to which the C=O bond coordinates, resulting in an inverse correlation between aldehyde adsorption and Au-Au bond distance. A simple trigonometric calculation shows that, for sp$^3$ hybridised C atoms, an Au–Au spacing of around 2.80 Å is optimal for Au–C distances of 2.16 Å, i.e. the most strongly bound clusters have geometries consistent with this bonding geometry at the C atoms.

Fig. 7 shows a comparison of the Au 5d partial density of states (PDOS) for the Au$_{13}$ cluster and associated Au$_{13}$O$_6$ structures. The bare Au$_{13}$ states range from around $-7$ to $-1$ eV relative to the Fermi level, consistent with the filled d-shell of atomic Au, whereas the Au$_{13}$O$_6$ PDOS plots show a broader spread of energies, with unoccupied states present above the Fermi level reflecting the formation of linear O–Au–O bonds and concomitant gold oxidation. Formation of empty metal d-states upon cluster oxidation permits localized adsorbate → metal donation as discussed above.

Further insight into the charge distribution of selected configurations was obtained using Bader analysis (Table 1). Fig. 7 shows that the Au$_{13}$ cluster has filled d-orbitals and so we would expect a net electron donation from the d-orbitals of the bare Au$_{13}$ cluster to adsorbed crotonaldehyde with negligible back-donation, however only minimal charge transfer ($\Delta q = 0.04$)
is actually calculated. It is worth recalling that gold NPs with odd numbers of electrons, such as the neutral Au13 cluster, exhibit high electron affinities due to the unpaired electron which formally occupies a delocalised state arising from the overlap of Au sp-atomic orbitals. This high electron affinity may allow electron transfer from crotonaldehyde to the cluster and confirm that for adsorbates possessing C=O bonds, it is repulsive steric interactions that regulate their adsorption over gold nanoparticles, with ethene less sensitive to such factors than the bulkier aliphatic aldehyde. We note here that the influence of surface oxygen atoms on the adsorption of ethene is considered for comparison with our crotonaldehyde results. The formation of a oxametallacycle akin to that discussed by Linic and Barteau for gold nanoparticles, with ethene less sensitive to such factors than the bulkier aliphatic aldehyde.

* Sum of Bader charges on indicated atom type. ⁵ Average Bader charge on indicated atom type. ⁶ Charge transfer, negative values indicate transfer from adsorbate to nanoparticle. ⁷ Bader charge on carbon atoms of C=C bonded to the cluster, in CrCHO C1 has a CH₃ and C2 a CHO substituent. ⁸ Bader charge on aldehyde oxygen atom.
The electronic effect of the substituents on the crotonaldehyde C=C bond can also be seen; even for the gas phase molecule the two C atoms have significantly different Bader charges. On adsorption both C atoms become slightly more negatively charged but this effect is in-sensitive to the state of the cluster. Further the charge on the aldehyde oxygen atom is practically unchanged from the gas phase for each adsorption mode suggesting that electronic rearrangement within the molecule upon adsorption plays a relatively minor role.

IV. Conclusions

In this study we find that oxidation of well-defined Au nanoparticles strongly influences crotonaldehyde and ethene adsorption. For the 0.8 nm diameter Au13 cluster discussed here, intermediate oxygen coverages enhance crotonaldehyde and ethene adsorption through the C=C group by 14–18 kJ mol⁻¹. This effect can be understood in terms of the genesis of empty Au d-states in the oxidised clusters able to receive electrons from these allylic adsorbates. At higher oxygen coverages this bonding picture is still valid, however steric interactions between oxygen adatoms neighbouring the crotonaldehyde (ethene) adsorption site destabilize the molecule by up to 60 kJ mol⁻¹ with respect to bare Au13. We also find that oxidation of these sub-nanometer gold NPs is likely to be favoured in an oxidising atmosphere, so that under normal selox conditions oxygen will be present on the surface.

Increasing the gold nanoparticle size to 1.1 nm (Au38) lowers the crotonaldehyde adsorption energy by 20–40% compared to the bare Au13 cluster. Oxidation to Au38O2⁺, wherein the O adatoms are located close to co-adsorbed crotonaldehyde, weakens the allylic aldehyde adsorption by as much as 90%.

These calculations highlight the importance of both the surface coverage, and location of adsorbed oxygen upon the stability of co-adsorbed crotonaldehyde, the desired product of crotyl alcohol selox. Oxygen bound in a three-fold hollow site adjacent to adsorbed crotonaldehyde dramatically destabilizes the latter due to strong steric repulsion. This finding implies that crotyl alcohol selox catalysed over gold nanoparticles should be conducted under high oxygen partial pressures, in order to desorb the reactively-formed aldehyde product and prevent side-reactions such as crotonaldehyde decarbonylation to propene and CO. Conversely, low oxygen partial pressures, and concomitant low surface oxygen coverages may hinder crotonaldehyde desorption due to enhanced adsorbate → cluster electron transfer relative to unoxidised gold nanoparticles.

Acknowledgements

We thank the EPSRC (EP/E046754/1; EP/G007594/3) for financial support and the award of a Leadership Fellowship (AFL) and studentship (AM). Computational resources for this project were partially provided by UK’s National high-performance computing service, HECToR (EP/F067496) through the materials consortium, ARCCA and HPC-Wales supercomputer facilities. We thank Dr Adam Thetford and Soon Wen Hoh for discussions on the charge analysis carried out as part of this work.
