Dynamics of photodissociation of XeF₂ in organic solvents†

Greg T. Dunning, a Thomas J. Preston, a Andrew J. Orr-Ewing, a,b Stuart J. Greaves, a Gregory M. Greetham, c Ian P. Clark c and Michael Towrie c

Transient electronic absorption measurements with 1 ps time resolution follow XeF₂ photoproducts in acetonitrile and chlorinated solvents. Ultraviolet light near 266 nm promptly breaks one Xe–F bond, and probe light covering 320–700 nm monitors the products. Some of the cleaved F atoms remain in close proximity to an XeF fragment and perturb the electronic states of XeF. The time evolution of a perturbed spectral feature is used to monitor the FXe–F complex population, which decays in less than 5 ps. Decay can occur through geminate recombination, diffusive separation or reaction of the complex with the solvent.

I. Introduction

Studying the photochemistry of small, solvated molecules presents a route to exploring the fundamental role of the surrounding medium in condensed-phase chemistry. In certain cases, the photoproducts are reactive, but isolating them in an inert solvent can provide a first step to interpreting their chemistry in reactive environments. Gas-phase photolysis of the precursor we use in the present work, xenon difluoride, produces XeF and a highly reactive F atom. Xenon difluoride itself is a strong oxidiser and effective fluorinating agent in organic and inorganic syntheses. For example, photolysis of XeF₂ acts as a light-driven oxidant of gold nanoparticles. Condensed-phase photolysis can parallel its gas-phase analogue, but the presence of the solvent can modify photodissociation dynamics in several ways. The surrounding molecules restrict the system from reaching complete separation, which can lead the nascent species to sample metastable complexes that can be non-intuitive to chemists. The solvent molecules can also affect the photochemistry by altering the electronic states involved in photolysis or by exchanging energy with the reactive complex during its separation. With small molecules like XeF₂ that have known spectroscopic features and relatively few reaction pathways, we can build on our chemical intuition of condensed-phase chemistry.

Our current effort uses time-resolved transient absorption spectroscopy to determine the condensed-phase dynamics and products of XeF₂ from 1 ps to 1.5 ns after photodissociation. This work provides ready analysis of XeF₂ as a source of F atoms for use in our on-going studies of liquid-phase bimolecular reaction dynamics. Following absorption of a 266 nm photon by XeF₂, homolytic fission of one Xe–F bond is predicted to dominate the gas-phase dynamics. Facile migration of photolytically released F atoms occurs in rare-gas matrices, but reaction with the solvent may limit the F-atom mobility in organic solvents.

Application of XeF in excimer lasers provided some original impetus for studying the ground and electronically excited XeF states. The electronic states of XeF that are important in 266 nm photolysis of XeF₂. One-photon absorption by XeF₂ leads to ground-state XeF through Xe–F bond cleavage, and its strong absorption to the B state near 345 nm provides a probe of the XeF photoproduct. The ground state is bound by about 1200 cm⁻¹ in the gas phase, and a large fraction of the XeF products remain bound well beyond the timescale of our measurement. The electronically excited states of XeF are ionic in character, and an F atom in the vicinity of XeF perturbs the optically bright B state. We use this known shift of the XeF spectrum as a marker for incomplete separation of the condensed-phase products, allowing us to follow with detail the condensed-phase dynamics that occur within the first few ps after photolysis of XeF₂.

II. Experimental approach

A. Transient absorption spectroscopy

The ULTRA Facility at the Central Laser Facility of the Rutherford Appleton Laboratory houses the apparatus we used to photolyse XeF₂ and to measure electronic-absorption spectra.
with 1 ps time resolution. The instrumentation used is unchanged from our recent study of chlorine-atom reactions\textsuperscript{19} and is described in detail elsewhere.\textsuperscript{20} A Ti:sapphire laser operating at 10 kHz generates both a 266 nm photolysis pulse and a white light continuum (WLC) probe pulse covering 320–700 nm, and an optical delay stage controls the relative timing, $D_t$, of their interaction with the liquid sample. A 512-element Si photodiode array measures the intensity of the spectrally dispersed broadband probe pulses. An optical chopper wheel modulates the photolysis pulse at 5 kHz for realtime background subtraction and normalisation.

Imperfect alignment of the beam along the optical delay line that controls the relative timing of photolysis and probe pulses can affect signal intensities at $D_t \gtrsim 100$ ps. To compensate for this we use the known excited-state lifetime of phenol in cyclohexane\textsuperscript{21} to apply a linear correction factor to the transient XeF\textsubscript{2} photolysis data we present. This correction yields long-time kinetics in the XeF\textsubscript{2} systems that are consistent with previous measurements.\textsuperscript{2} The spectra are not corrected for the temporal chirp in the WLC: instead, data for time delays $<1$ ps are excluded from analysis.

The solute XeF\textsubscript{2} is fragile, and keeping samples colder than 290 K before and during measurements helps ensure its stability. Dried glassware, solvents, and sample holders prevent unwanted side reactions between XeF\textsubscript{2} and water. Rapid thermal reaction of the possible contaminant XeF\textsubscript{4} with solvent\textsuperscript{5} ameliorates its effect on our measurements. Acquiring a pre-determined set of time delays between photolysis and probe pulses in random order further reduces the effects of longer timescale changes in the sample on our measurement. Dilute solutions of 0.25 M XeF\textsubscript{2} (> 99.9\% trace metal basis, Sigma Aldrich) in dried CH\textsubscript{3}CN, CCl\textsubscript{4}, CDCl\textsubscript{3}, or CD\textsubscript{2}Cl\textsubscript{2} pass through a sealed flow system. A rastering sample cell, consisting of CaF\textsubscript{2} windows separated by a 0.2 mm PTFE spacer, ensures that each laser pulse interrogates a fresh sample volume.

B. Computational methods

Calculations of both the XeF\textsubscript{2} and XeF systems enhance our understanding of the XeF\textsubscript{2} photophysics. Excited-state CASMPT calculations followed by CASPT2 correction, of the XeF\textsubscript{2} potential energy surface use the aug-cc-pVDZ\textsuperscript{22} basis set for F atoms and the ECP46MWB effective core potential for Xe. Calculations were implemented with use of the MOLPRO program.\textsuperscript{23} This treatment is an effective quasi relativistic model for the large Xe core and has proven successful in modelling the stability of Au\textsuperscript{1+}–Xe complexes.\textsuperscript{24} We also replicate the XeF X and B states using known constants\textsuperscript{10} to calculate the vibrational wavefunctions through an RKR analysis.\textsuperscript{25} The electronic absorption spectrum of vibrationally excited XeF is then simulated through a Frank–Condon analysis with use of the Level programme.\textsuperscript{26}

III. Results and discussion

A. XeF from XeF\textsubscript{2}

The steady state absorption spectrum of gas phase XeF\textsubscript{2} is shown in Fig. 2, and is fraught with multiple features and...
possible dissociation products. The lowest energy electronic absorption, which has a maximum near 240 nm, populates the \( \Sigma_u \) state and promptly produces XeF(X) + F.\(^2,6\) Photolysis at 266 nm, about 4.6 eV of excitation, also makes Xe + F\(_2\) and Xe + 2F energetically available, but previous studies have not directly observed these more complicated dissociation pathways.\(^27\) Absorbing two photons, which we show below to be unlikely in our experiment, could produce XeF in electronically excited states.

Previous work has identified the condensed-phase XeF absorption spectrum in both steady-state cryogenic matrices\(^{16,28}\) and in liquid samples of photolyzed XeF\(_2\).\(^7\) We use these prior assignments to guide the interpretation of our measurements, which are the first to follow this process on the ps to ns timescale. Ground-state XeF isolated in cryogenic rare gas matrices shows a broad absorption feature near 320 nm. This feature is the B \( \leftrightarrow \) X transition, which lies approximately 4000 \( \text{cm}^{-1} \) lower in energy than in the gas phase.\(^{16,22}\) Photolysis of XeF\(_2\) at 266 nm in CD\(_3\)CN produces XeF with a sharp feature near 345 nm.\(^2\) XeF has a 25 \( \mu \text{s} \) lifetime in acetonitrile, and our transient absorption spectrum at \( \Delta t = 500 \text{ ps} \) matches the previously measured spectrum at \( \Delta t = 100 \text{ ns} \).\(^2\) Because the spectrum is largely unchanged between our longest time delay and ns to \( \mu \text{s} \) intervals, we take our long-time spectrum to represent the equilibrated XeF photoproduct.

It is necessary to verify that one-photon absorption dominates our condensed-phase study. Photolysis with ns laser pulses at 266 nm and intensities greater than \( 9 \times 10^{12} \text{ W cm}^{-2} \) saturates the transition to the \( \Sigma_u \) state and ensuing absorption of a second photon produces electronically excited XeF(B) and an F atom.\(^29\) Our photolysis intensity of about \( 1 \times 10^{12} \text{ W cm}^{-2} \) is ten times smaller than the onset of two-photon absorption.\(^29\) The integrated area of the transient absorption feature at \( \Delta t = 500 \text{ ps} \), which measures XeF from photolysis of XeF\(_2\), as a function of photolysis pulse energy,\(^2\) produces a linear dependence within the range 0.25–2.5 \( \times 10^{12} \text{ W cm}^{-2} \), spanning more than an order of magnitude of attenuation below the onset of two-photon absorption.\(^29\) Therefore we conclude that transient signals measured and shown here result from one-photon absorption leading to the XeF(X) + F photodissociation pathway.

Decomposition to Xe + F\(_2\) is a lower energy channel than XeF + F production and so might compete following UV excitation of XeF\(_2\). We discount contributions to the transient spectra from this pathway because F\(_2\) absorbs only weakly in the observable, 320–700 nm region\(^10\) and the strong Xe – F\(_2\) \( \rightarrow \) Xe\(^*\) – F\(_2\) charge transfer band lies to much shorter wavelength. In liquid xenon, for example, the band is observed below 185 nm.\(^31,32\)

### B. Electronic states of XeF and FXe–F

The XeF B – X absorption was also observed in CD\(_2\)Cl\(_2\), CDCl\(_3\) and CCl\(_4\) solvents and the maximum of each spectrum shifts monotonically with the dielectric constant of the solvent, \( \varepsilon_r \). The polar solvents preferentially solvate the ion-pair B state of XeF relative to its X state,\(^18\) decreasing the energy of the transition. Apkarian and co-workers\(^18\) showed that the Onsager reaction-field description of the stabilization of a point dipole in a dielectric cavity\(^33,34\) captures the essence of the energy shift of the B state.\(^18\) In this model, the change in energy of the solvated B state relative to the gas phase, \( \Delta E \), is

\[
\Delta E = -\frac{1}{4\pi\varepsilon_0\varepsilon_r} \frac{2(\mu - 1)}{2\varepsilon_0 + 1} \frac{1}{r^3},
\]

with the dipole moment of the B state, \( \mu \), and radius, \( r \), of the host cavity in the solvent as the only molecular parameters.

The XeF(B – X) absorption spectra from the current work fit the general trend of eqn (1), as shown in Fig. 3, providing a two-fold lesson that we carry forward to our interpretation of the transient electronic absorption spectra in the next section. First, because eqn (1) only applies to the B state of XeF yet gives reasonable agreement with observed trends, electrostatic effects perturb the ion-pair B state more than the covalent ground state. Second, we can use the time evolution of the XeF absorption spectrum as a reporter of the dynamic local electrical environment\(^18\) as the system evolves from XeF\(_2\) to photolysis products.

One factor perturbing the XeF spectrum is the electron-negative F-atom photoprodut of XeF\(_2\). Because some photolysis events lead to incomplete separation of the XeF and F fragments, we observe the spectral signatures of the metastable Fxe–F complex. This complex is stable in rare-gas matrices at 20 K and indeed influences the B state.\(^18\) Apkarian and co-workers first described how the F atom decreases the energy gap between the XeF(X) and XeF(B) states and labelled this altered state XeF(B\(^*\)).\(^18\) shown by the red line in Fig. 1.

Fig. 4 shows the results of our calculations of the isolated Fxe–F complex, as detailed in the Experimental Approach, and they provide an extension of the original description of the electronic states in the Fxe–F complex.\(^18\) We label the states of the complex as they correlate to the X, A, and B states of XeF at large Fxe–F separation. The figure displays the results of calculations with linear F\(_x\)-Xe–F\(_n\) geometries and a fixed F\(_x\)-Xe bond length at its calculated minimum of 2.3 \( \text{Å} \), which is in agreement...
XeF(B–X) and XeF(A) potentials are observed in the A and B states with the red shifted B*–X absorption band. The shape of the prompt feature, which extends from the visible to the ultraviolet, is consistent with electronic states of XeF2-F shown in Fig. 4. At an FXe–F distance of about 2.9 Å, the calculated B*–X energy gap goes through a minimum that corresponds to a 361 nm long-wavelength absorption cutoff. Longer and shorter distances have larger energy gaps, which could account for the broad extension of the feature to shorter wavelength. The Franck–Condon-active mode of the absorption is likely to be stretching between the F3Xe pair, which is orthogonal to the plotted coordinate. Thus, the intensity of the transition could remain relatively constant over all Xe–F3 distances, reflected by the flat-topped prompt absorption. The overestimate of the energy gap, however, is attributed to the gas-phase nature of the calculation. Exploring the effects of other FXe–F degrees of freedom or the solvent is beyond the scope of the current work, but we expect the general trends presented in these isolated molecule calculations to apply to the current condensed phase study.

Absorption to the A state of XeF may be discounted as a source of the longer wavelength absorption, because it has a gas-phase band origin near 1400 nm.16 Other candidates for the prompt absorption that we rule out include vibrationally excited XeF, charge-transfer transitions between XeF or F and the solvent or between Xe atoms and F2 (see earlier), and excited-state absorptions of XeF or XeF2. A spectral simulation of the XeF X and B states using previously derived spectroscopic constants15,18 shows that populating up to the highest bound vibrational level of XeF shifts the gas-phase spectrum by only 14 nm, which is incongruous with our observation. Both XeF-to-CD3CN and
F-to-CD$_3$CN charge-transfer transitions have calculated high intensities outside our probe range as discussed in the ESI.$^\dagger$

The B state of XeF has a 14 ns gas phase lifetime,$^{35}$ raising the possibility of an excited state absorption. As Fig. 2 describes, the absorption of 1 photon at 266 nm does not allow for population of an electronically excited state of XeF, which discounts the absorption out of this excited state. Equally excited state absorptions of XeF$_2$ may be removed as a possible source of the long wavelength absorption, as no energetically accessible bound states of XeF$_2$ are known to exist.$^{27}$

Global fitting of the transient absorption spectra in Fig. 5 through deconvolution of the prompt XeF(B$^*$–X) and long-lived XeF(B–X) spectral signatures provides ready analysis of the kinetics of the system. At all times after photolysis $t$, we fit the spectrum, $S(\lambda,t)$ to a sum of two spectral features,

$$S(\lambda,t) = A(t)P(\lambda) + [B(t)\text{erf}(\lambda) + S_0(t)].$$ (2)

Because the spectrum at $\Delta t \geq 500$ ps results from only XeF(B–X) absorption, and our spectral simulation described in the ESI$^\dagger$ indicates that the XeF(B–X) spectrum changes inappreciably with excess internal energy, we treat the long-time spectrum as the basis for fitting the time-invariant XeF(B–X) spectrum, $P(\lambda)$. The function $P$ is a Voigt profile fit to the average 1000 ps $\leq \Delta t \leq 1500$ ps spectra. We use an error function to model the evolution of the prompt spectrum not to describe a particular model, but because it requires few floating parameters and captures the general appearance of this feature that extends beyond our probe range. The amplitude of the long-time absorption, $A(t)$, directly reports on the free XeF population, and an integral of the error function with combined offset and amplitude scaling factor $B(t)$ provides an estimate of the FXe–F complex population.

The deconvoluted time evolution of the XeF and FXe–F features, shown in Fig. 6 as $A(t)$ in black and $\int_{-\infty}^{\infty} [B(\lambda)\text{erf}(\lambda) + S_0(t)]d\lambda$ in red, faithfully represents the kinetics of the raw spectra of Fig. 5. The rapid rise of the XeF(B$^*$–X) feature shows that the FXe–F complex forms within our time resolution, which is about 1 ps. It is also possible for the liberated F atom to escape the vicinity of the XeF co-fragment directly, similar to the facile migration reported for F atoms in rare gas matrices.$^{13}$ The kinetic scheme used to model the data is described below, with fits to the model shown as solid lines in Fig. 6.

$$\begin{align*}
\text{XeF}_2 & \xrightarrow{k_1} \text{FXe–F complex} \\
\text{XeF}_2 & \xrightarrow{k_2} \text{XeF(X)} + \text{F} \\
\text{XeF–F complex} & \xrightarrow{k_3} \text{XeF(X)} + \text{F} \quad \text{(or DF from reaction with solvent)}
\end{align*}$$

The kinetic model described allows for initial photodissociation of XeF$_2$ to produce either the FXe–F complex (with rate coefficient $k_1$) or XeF(X) and an escaped F atom ($k_2$). The complex can subsequently dissociate to form XeF(X) + F or react with the solvent ($k_3$), and we observe both a rise in XeF(B–X) absorption and build-up of DF (the latter by transient IR absorption spectroscopy$^{36}$). The model is fitted to the time-dependent relative yields of XeF(X) and FXe–F by numerical integration.

The above scheme neglects some plausible competing loss processes for the FXe–F complex. For example, work in Ar and Ne liquids observed XeF$_2$ growth from FXe–F decay, although this pathway was cut off upon matrix isolation. This recombination of the FXe–F complex is not included explicitly in our analysis because we have no spectral signature for XeF$_2$ recovery. Similarly, our experiments are insensitive to reactive decomposition of FXe–F to Xe + F$_2$ because the charge-transfer band is outside our spectral window, while the near-UV band of F$_2$ is weak and we see no evidence for build-up of this stable molecule in our spectra. However, we recognise that these unobserved pathways could contribute to the magnitude of $k_3$ as additional loss pathways for FXe–F. Fits of the experimental absorption band intensities to the kinetic model produce the rate coefficients reported in Table 1.

D. Dynamics of photoproducts

The rate coefficients in Table 1 are consistent with the dissociation of XeF$_2$ yielding XeF and F, either as a complex or as...
separated fragments, in less than 1 ps. It is difficult to make an assessment of branching among the prompt photoproduct pathways because the breadth of the prompt feature obscures the region where XeF absorbs most strongly. Furthermore, we do not probe the full FXe–F spectrum, and so we detect only a portion of these products. The decay of this feature may not occur uniformly over all wavelengths, and relative oscillator strengths are not known. The values of $k_1$ and $k_2$ are not well determined because of the 1 ps experimental time resolution. For CD$_3$CN solutions, the low XeF band intensity in the first few ps after photolysis, creating a negligible rate coefficient for direct production of separated XeF and F, may result from two different factors.

First, if very few F atoms escape the solvent cage ballistically, and nearly all remain trapped within the cage, most of the prompt photoproduct will appear as the FXe–F complex. Small atoms and fragments such as H and CN are known to find their way directly through the solvent cage, and F atoms show high mobility in inert matrices, so we expect some fraction of direct F-atom separation. However, different solvents have a significant influence upon the quantum yield of in-cage recombination. Highly polar solvents such as H$_2$O show large in-cage recombination quantum yields of ~70% for ICN photolysis, in comparison to ~30% in the less polar CHCl$_3$. It is thus reasonable to expect a large proportion of the XeF and F fragments to become trapped within the CD$_3$CN solvent cage immediately after dissociation.

Second, the impulse of photolysis may impart so much rotational and vibrational energy in the XeF fragment that broadening to the XeF(B–X) absorption, estimated to be as large as 40 nm FWHM, may occur (ESI†). We are unable to separate any such broadened XeF signal from the FXe–F complex feature and therefore cannot make a direct assessment of the importance of this process.

Loss of FXe–F complexes may follow a few competing pathways, of which one is geminate recombination to XeF$_2$. In the previous work that identified the FXe–F complex, the rigid Ar or Ne matrix at 20 K prevented relaxation to linear XeF$_2$, suggesting a small barrier to recombination. Our time-resolved measurements detect FXe–F that is prevented from reforming XeF$_2$, but cannot discriminate between dynamical or energetic causes. However, the commensurate decay of the FXe–F band and growth of the XeF feature, and the near-isosbestic point evident in Fig. 5 hint that a significant proportion of the FXe–F survives recombination and instead decays by other routes.

The delayed cage escape and reactive pathways would be expected to have individual rates that depend upon the complex stability and any barrier to reaction. Time-resolved infra-red absorption spectra, reported elsewhere, show build-up of DF product on a timescale that is consistent with the decay of the FXe–F band and rise of the XeF(X) band intensities. We conclude that the reaction of the F atom with the solvent is a substantial loss pathway for the complex, and the rate coefficient $k_3$ represents the sum of this reactive loss, the dissociation of the complex and its recombination to XeF$_2$.

### E. Photolysis of XeF$_2$ in chlorinated solvents

The transient absorption spectra in Fig. 7 result from XeF$_2$ photolysis in CD$_2$Cl$_2$, CDCl$_3$, and CCl$_4$ solvents. Photolysis of these chlorinated solvents at 266 nm also produces transient photoproducts with absorption features in the UV/Vis region. Subtracting those features from our transient spectra with XeF$_2$, acquired under identical conditions, produces signals resulting only from solute-dependent photo-chemistry. In all these chlorinated solvents, it is evident that the majority of the photolysis of XeF$_2$ occurs in less than a picosecond.

We fit the transient spectra in CD$_2$Cl$_2$, but not the other two solvents, to eqn (2) because there is definite separation between the two transient features. The integrated intensities are then simultaneously fitted to the kinetic model described above, as

![Fig. 7](image-url)
shown in Fig. 6. Unlike in acetonitrile, the XeF(X) feature near 350 nm appears promptly after photolysis in these solvents and the FXe–F complex is not as evident in CDCl3 or CCl4. Less clearcut signatures of the complex in these two solvents may be explained by shifts in the FXe–F band to shorter wavelength, a decrease in the branching ratio of complex formation, or an increase in the rate of the loss of the complex.

The rate coefficients extracted from the fit of the integrated band intensities following photolysis of XeF2 in CD2Cl2 are displayed in Table 1. The direct production of XeF(X) shows a significant rate coefficient of 0.63 ± 0.33 ps⁻¹, while the complex decay shows a time constant similar to that for XeF2 photolysis in acetonitrile. The near identical timescales for complex loss suggest that the stability of the complex to decay (whether by reaction or other pathways discussed earlier) is unchanged upon changing solvent. Reaction with the CD2Cl2 is most likely to produce DF because we see no evidence for the B–X absorption band of ClF near 480 nm in the transient spectra. The known selectivity of gas-phase reactions of F atoms with chloroform and dichloromethane supports this deduction.

Any difference in the observed FXe–F complex yields between the chlorinated solvents and acetonitrile may result from two distinct mechanisms:

1. The photolytically produced F atom immediately escapes from the solvent cage. Ballistic escape can be affected by the ability of the solvent to quench the excess energy from the system, the mobility of F atoms in the solvent, and the strength of the solvent cage.

2. The probability of prompt recombination to XeF2 increases within the chlorinated solvents. However, the origins of any barrier to recombination are uncertain, so we draw no conclusion about this trend.

The XeF molecule is observed to have a nanosecond or longer stability in CD3CN and CCl4 solvents but there is a substantial loss channel in CDCl3 and CD2Cl2. We suggest that the XeF reacts with the solvent to produce DF, and our transient IR absorption studies support this interpretation. Time constants for the loss of the XeF molecule are found to be 800 ± 200 ps in CD2Cl2 and 350 ± 50 ps within CDCl3.

The XeF B–X absorption in CCl4 solvent is observed to shift to shorter wavelength with a 4.1 ± 0.3 ps time constant, which may be indicative of vibrational cooling of the XeF. The XeF(X) ground state potential supports ~8 vibrational levels. However, in CD3CN and CD2Cl2 solvents the FXe–F complex feature obscures any spectral signatures of vibrational relaxation dynamics.

IV. Conclusions

Photodissociation of XeF2 in organic solvents produces XeF(X) and F with a time constant of less than 1 ps. If confined within the same solvent cage, the nearby photolytically produced F atom perturbs the ionic B state of the XeF molecule, which allows the formation of these FXe–F complexes to be observed spectrscopically. Such complexes have previously been observed in Ar and Ne matrices. The FXe–F is expected to be only weakly bound, and the decay of its spectral band provides information on the reactive removal of F atoms. The perturbed XeF(B*–X) spectral band of the FXe–F complex appears immediately after photolysis in CD3CN, while significant free XeF(X) is observed promptly in CD2Cl2. The perturbed signal assigned to the FXe–F decays with a time constant of 4.0 ± 0.2 ps in CD3CN and 4.5 ± 0.8 ps in CD2Cl2. Much of the decay of the complex is expected to occur through D atom abstraction reactions with the solvent to produce DF. Spectral features of the FXe–F complex are less clear, or absent, for XeF2 photolysis in CDCl3 or CCl4.

The XeF molecule is stable in CD3CN and CCl4 solvents for nano- to microseconds. Substantial loss channels of XeF in CDCl3 and CD2Cl2 solvents are suggestive of reaction with the solvent.

Acknowledgements

We thank Dr D. P. Tew, University of Bristol for help with CASPT2 calculations. The Bristol group gratefully acknowledges financial support from the EPSRC (Programme Grant EP/G00224X) and the ERC (Advanced Grant 290966 CAPRI). Experimental measurements were conducted at the ULTRA facility which is supported by STFC (Facility Grant ST/501784).
