A partial differential equation for pseudocontact shift

G. T. P. Charnock^a and Ilya Kuprov^{*b}

It is demonstrated that pseudocontact shift (PCS), viewed as a scalar or a tensor field in three dimensions, obeys an elliptic partial differential equation with a source term that depends on the Hessian of the unpaired electron probability density. The equation enables straightforward PCS prediction and analysis in systems with delocalized unpaired electrons, particularly for the nuclei located in their immediate vicinity. It is also shown that the probability density of the unpaired electron may be extracted, using a regularization procedure, from PCS data.

Introduction

Pseudocontact shift (PCS) is an effective additional contribution to the nuclear chemical shift that arises in open-shell chemical systems due to partial polarization of the electron spin by the applied magnetic field.¹ The primary application of PCS is in structural biology, where it provides additional distance restraints for molecular geometry determination.^{2,3} *Pseudocontact* shift is different from the *contact* shift in that it does not require electron-nuclear overlap and propagates instead through the dipolar coupling.¹

It can be verified by direct inspection that the commonly used point electron dipole expression for the PCS⁴ has a zero Laplacian everywhere except the origin:

$$\sigma_{\text{PCS}}^{(\text{point})} = \frac{1}{12\pi} \left[\Delta\chi_{\text{ax}} \frac{2z^2 - x^2 - y^2}{r^5} + \frac{3}{2} \Delta\chi_{\text{rh}} \frac{x^2 - y^2}{r^5} \right]; \quad (1)$$

$$\nabla^2 \sigma_{\text{PCS}}^{(\text{point})} = 0$$

where $\Delta\chi_{\text{ax}}$ and $\Delta\chi_{\text{rh}}$ are axially and rhombicity of the electron magnetic susceptibility tensor χ and the nucleus is located at $[x, y, z]$ relative to the electron. This is to be expected – all classical electromagnetic phenomena must obey Maxwell's equations – but the singularity at the origin also suggests the possibility of an elliptic partial differential equation existing for the harder case of the PCS generated by a *non-point* electron probability density $\rho(\vec{r})$:

$$\sigma_{\text{PCS}}^{(\text{non-point})} = \int \sigma_{\text{PCS}}^{(\text{point})}(\vec{r} - \vec{r}') \rho(\vec{r}') d^3\vec{r}';$$

$$\nabla^2 \sigma_{\text{PCS}}^{(\text{non-point})} = \kappa(\chi, \vec{r}) \quad (2)$$

in which the source term $\kappa(\chi, \vec{r})$ is unknown and has so far resisted all derivation attempts: a direct calculation of the

Laplacian of the convolution of eqn (1) with a finite unpaired electron density comes across singular integrals that cannot be regularized.⁵ Yet the prize is tempting – elliptic PDEs are a classical topic in mathematics: a simple enough equation would generalize all PCS prediction and analysis problems, improve data interpretation close to the unpaired electron and enable direct measurement of spin label probability distributions in double electron-electron resonance (DEER) experiments.⁶ It would also be convenient – numerical PDE solvers are standard functionality in modern technical computing software. In this communication we derive the equation and comment on some of its properties.

Hyperfine shift as a total energy derivative

To facilitate subsequent mathematics, and also for the sake of completeness, we provide in this section succinct derivations, using the relatively modern total energy derivative formalism,⁷ of the classical expressions for the various components of the hyperfine shift tensor.^{1,4} For historical reasons we shall separate the *hyperfine shift tensor* σ_{HF} into the *contact shift tensor* σ_{CS} and the *dipolar shift tensor* σ_{DS} . Their isotropic parts shall be called *contact shift* and *pseudocontact shift*, and denoted σ_{CS} and σ_{PCS} respectively.

Placed in a magnetic field \vec{B}_0 , a point electron at the origin with a magnetic susceptibility tensor $\chi \ll 1$ would acquire an average magnetic moment:

$$\vec{\mu}_{\text{e}} = \chi \cdot \vec{B}_0 / \mu_0 \quad (3)$$

The additional magnetic field \vec{B}_1 generated by this dipole at the point \vec{r} is:

$$\vec{B}_1 = \frac{\mu_0}{4\pi} \left[3 \frac{\vec{r} \otimes \vec{r}^T}{r^5} - \frac{1}{r^3} \right] \cdot \vec{\mu}_{\text{e}} = \frac{1}{4\pi} \left[3 \frac{\vec{r} \otimes \vec{r}^T}{r^5} - \frac{1}{r^3} \right] \cdot \chi \cdot \vec{B}_0 \quad (4)$$

^a Oxford e-Research Centre, University of Oxford, 7 Keble Road, Oxford OX1 3QG, UK

^b School of Chemistry, University of Southampton, Highfield Campus, Southampton, SO17 1BJ, UK. E-mail: i.kuprov@soton.ac.uk

The change in energy E for a nuclear magnetic dipole $\vec{\mu}_N$ located at that point would be:

$$E = -\vec{\mu}_N^T \cdot \vec{B}_1 = -\frac{1}{4\pi} \vec{\mu}_N^T \cdot \left[3 \frac{\vec{r} \otimes \vec{r}^T}{r^5} - \frac{1}{r^3} \right] \cdot \chi \cdot \vec{B}_0 \quad (5)$$

and therefore, the additional chemical shift tensor experienced by the nucleus, measured relative to the unperturbed conditions, would be:

$$\sigma_{DS} = -\frac{\partial^2 E}{\partial \vec{\mu}_N^T \partial \vec{B}_0} = \frac{1}{4\pi} \left[3 \frac{\vec{r} \otimes \vec{r}^T}{r^5} - \frac{1}{r^3} \right] \cdot \chi \quad (6)$$

where the minus appears because of the relationship between chemical shielding and chemical shift.^{8,9} The isotropic part of this tensor is:

$$\sigma_{PCS} = \frac{1}{3} \text{Tr}(\sigma) = \frac{1}{12\pi} \text{Tr} \left(\left[3 \frac{\vec{r} \otimes \vec{r}^T}{r^5} - \frac{1}{r^3} \right] \cdot \chi \right) \quad (7)$$

For a point electron located at \vec{r}_e and a point nucleus located at \vec{r}_N the final expression is:

$$\sigma_{PCS}(\vec{r}_N, \vec{r}_e) = \frac{1}{12\pi} \text{Tr} \left(\left[3 \frac{(\vec{r}_N - \vec{r}_e) \otimes (\vec{r}_N - \vec{r}_e)^T}{|\vec{r}_N - \vec{r}_e|^5} - \frac{1}{|\vec{r}_N - \vec{r}_e|^3} \right] \cdot \chi \right) \quad (8)$$

A neat derivation for the hyperfine shift can also be given in terms of the hyperfine coupling tensor \mathbf{A} . The spin Hamiltonian for the hyperfine interaction is $\hat{H} = \hat{L} \cdot \mathbf{A} \cdot \hat{S}$ and therefore the corresponding energy change for the k -th nucleus in the system is:

$$E = \frac{\vec{\mu}_n^{(k)} \cdot \mathbf{A}^{(k)} \cdot \vec{\mu}_e}{\gamma_e \gamma_n^{(k)} \hbar} = \frac{\vec{\mu}_n^{(k)} \cdot \mathbf{A}^{(k)} \cdot \chi \cdot \vec{B}_0}{\mu_0 \gamma_e \gamma_n^{(k)} \hbar} \quad (9)$$

After using the same derivative expression for the chemical shielding,⁷ we obtain:

$$\begin{aligned} \sigma_{CS}^{(k)} + \sigma_{DS}^{(k)} &= -\frac{\mathbf{A}^{(k)} \cdot \chi}{\mu_0 \gamma_e \gamma_n^{(k)} \hbar}, \\ \sigma_{CS}^{(k)} + \sigma_{PCS}^{(k)} &= -\frac{1}{3} \text{Tr} \left[\frac{\mathbf{A}^{(k)} \cdot \chi}{\mu_0 \gamma_e \gamma_n^{(k)} \hbar} \right] \end{aligned} \quad (10)$$

A significant advantage of these equations over other physically equivalent formulations is that the excitation structure of the quantum chemistry part of the problem is hidden from the user – both the hyperfine tensor and the susceptibility tensor are effective quantities that already incorporate all of the formidable complexities of the electronic structure theory.⁷ The derivations given above are classical, but the only assumption in eqn (10) is that $\chi \ll 1$ (meaning also that magnetic hyperpolarizability terms in the electronic structure theory are negligible) and that the electron relaxes sufficiently rapidly for eqn (3) to always remain valid.

Eqn (8), in its various forms, has done considerable service to the NMR community over the last forty years – naturally occurring calcium, magnesium and other metals in biological systems can often be substituted with lanthanides and pseudocontact shift then used to obtain distance restraints for

structure determination purposes.^{2,3} The point electron dipole assumption does, however, have its validity range – eqn (8) is not applicable in close proximity of the metal centre, most notably in lanthanide spin labels, and also in the cases where the electron probability density is broadly distributed within the molecular structure.

Derivation of the elliptic PDE

The source term $\kappa(\chi, \vec{r})$ in eqn (2) for pseudocontact shift induced by a distributed electron is not currently known. The most straightforward derivation is to notice that:

$$3 \frac{(\vec{r}_N - \vec{r}_e) \otimes (\vec{r}_N - \vec{r}_e)^T}{|\vec{r}_N - \vec{r}_e|^5} - \frac{1}{|\vec{r}_N - \vec{r}_e|^3} = \frac{\partial^2}{\partial \vec{r}_e \partial \vec{r}_e^T} \frac{1}{|\vec{r}_N - \vec{r}_e|} \quad (11)$$

and to note that the Laplacian of the reciprocal distance is:

$$\nabla_N^2 \frac{1}{|\vec{r}_N - \vec{r}_e|} = -4\pi \delta^3(\vec{r}_N - \vec{r}_e) \quad (12)$$

With these observations in place, we can conclude that:

$$\nabla_N^2 \sigma_{PCS}(\vec{r}_N, \vec{r}_e) = -\frac{1}{3} \text{Tr} \left(\left[\frac{\partial^2}{\partial \vec{r}_e \partial \vec{r}_e^T} \delta^3(\vec{r}_N - \vec{r}_e) \right] \cdot \chi \right) \quad (13)$$

The convolution of this expression with a finite electron probability density distribution $\rho(\vec{r}_e)$ then yields (after dropping the N subscript on the nuclear coordinate vector \vec{r}_N):

$$\nabla^2 \sigma_{PCS}(\vec{r}) = -\frac{1}{3} \text{Tr} \left(\left[\frac{\partial^2 \rho(\vec{r})}{\partial \vec{r} \partial \vec{r}^T} \right] \cdot \chi \right) \quad (14)$$

After abbreviating the Hessian of $\rho(\vec{r})$ in square brackets

$$\mathbf{H}_\rho = \frac{\partial^2 \rho(\vec{r})}{\partial \vec{r} \partial \vec{r}^T} \quad (15)$$

we arrive at a neat final result:

$$\nabla^2 \sigma_{PCS} = -(1/3) \text{Tr}[\mathbf{H}_\rho \cdot \chi] \quad (16)$$

A similar derivation for the full 3×3 dipolar shift tensor in eqn (6) yields:

$$\nabla^2 \sigma_{DS} = -\mathbf{H}_\rho \cdot \chi \quad (17)$$

If chemical *shielding* is considered instead of the chemical *shift*, the minus sign on the right hand side disappears. Simplicity of eqn (16) and (17) stands in sharp contrast with the unfathomable spherical harmonic expansions¹⁰ generated by *ab initio* treatments using the ligand field theory. It should be noted that eqn (16) and (17) only apply to pseudocontact and dipolar shift respectively. For contact shifts a convenient description is provided by eqn (10), where the isotropic part of the hyperfine tensor is proportional to the local spin density.

Analytical and numerical solutions

General solution strategies for eqn (16) and (17) are identical to those of Poisson's equation.¹¹ The special case of the point

electron in eqn (7) is recovered by observing that the Green's function of the Laplacian is:

$$\nabla^2 G(\vec{r}, \vec{r}') = \delta^3(\vec{r} - \vec{r}') \Rightarrow G(\vec{r}, \vec{r}') = -\frac{1}{4\pi} \frac{1}{|\vec{r} - \vec{r}'|} \quad (18)$$

and taking its convolution with the right hand side of eqn (16) for the point electron:

$$\begin{aligned} \sigma_{\text{PCS}} &= \frac{1}{12\pi} \int \frac{1}{|\vec{r} - \vec{r}'|} \text{Tr} \left[\frac{\partial^2}{\partial \vec{r}'^T \partial \vec{r}'} \delta^3(\vec{r}') \chi \right] d^3 \vec{r}' \\ &= \frac{1}{12\pi} \text{Tr} \left[\frac{\partial^2}{\partial \vec{r}^T \partial \vec{r}} \frac{1}{|\vec{r}|} \chi \right] \\ &= \frac{1}{12\pi} \text{Tr} \left(\left[3 \frac{\vec{r} \otimes \vec{r}^T}{r^5} - \frac{1}{r^3} \right] \cdot \chi \right) \end{aligned} \quad (19)$$

Analytical treatments of more general unpaired electron probability density distributions may be simplified significantly by noting that the Laplacian in eqn (16) and (17) leaves spherical harmonics intact. General solutions of those equations therefore simply inherit the multipolar expansion from the source term in the same way as Poisson's equation solutions do:¹²

$$\begin{aligned} \sigma(r, \theta, \varphi) &= \frac{1}{4\pi} \sum_{l=0}^{\infty} \sum_{m=-l}^l (2 - \delta_{m0}) \frac{(l-m)!}{(l+m)!} \left(\frac{1}{r}\right)^{l+1} P_l^m(\cos \theta) \\ &\quad \times (a_{lm} \cos m\varphi + b_{lm} \sin m\varphi) \end{aligned} \quad (20)$$

$$a_{lm} + ib_{lm} = \int_{\mathbb{R}^3} \kappa(\chi, \vec{r}) r^l P_l^m(\cos \theta) e^{im\varphi} dV$$

where $\kappa(\chi, \vec{r})$ is either the right hand side of eqn (16), or each of the nine matrix elements on the right hand side of eqn (17).

This is the general *analytical* solution for eqn (16) and for each matrix element of eqn (17), but in practice the interpretation of multipole moments with $l > 2$ is difficult. We would argue here that *numerical* treatment is easier computationally and also more interpretable from the physical point of view because the fundamental quantity there is the unpaired electron probability density $\rho(\vec{r})$. Sparse matrix representations of 3D Laplacians with Dirichlet, Neumann or periodic boundary conditions are readily available,¹³ and the numerical solution of eqn (16) and (17) requires a single sparse matrix-inverse-times-vector operation:

$$\sigma_{\text{PCS}} = -(1/3) \mathbf{L}^{-1} \text{vec}[\text{Tr}(\mathbf{H}_\rho \cdot \chi)] \quad (21)$$

where \mathbf{L} is a matrix representation of the 3D Laplacian with appropriate boundary conditions¹³ and $\text{vec}[\text{Tr}(\mathbf{H}_\rho \cdot \chi)]$ denotes the index transformation that stretches $[\text{Tr}(\mathbf{H}_\rho \cdot \chi)]$, which is a three-dimensional array, into a column vector. Eqn (21) has been implemented into versions 1.5 and later of our *Spinach* library.¹⁴

A practical example of pseudocontact shift field being computed for a lanthanide complex using eqn (16) is shown in Fig. 1. Nuclear coordinates, electron probability density and the susceptibility tensor have all been estimated using DFT methods in Gaussian09 (see figure caption for the details of the methods used). The conclusion from Fig. 1 is, at least for this complex, that the accuracy of the point PCS model is very high, presumably due to the localized nature of the f orbitals under the relatively low

Fig. 1 An example of the forward problem solution and a demonstration of the mutual consistency of eqn (8), (10) and (17). The red points refer to the symmetry-unique atoms in the ligand, including carbons and protons, but excluding nitrogens that have significant contact shifts. (A) Point model *versus* the elliptic PDE in eqn (16) for the PCS in the complex of europium(III) with 1,4,7,10-tetrakis(2-pyridylmethyl)-1,4,7,10-tetraazacyclododecane²⁴ using the magnetic susceptibility tensor obtained from a DFT calculation. (B) Point model *versus* the PCS part of eqn (10) using hyperfine tensors and the magnetic susceptibility tensor from a DFT calculation. (C) Volumetric stereo plot of the PCS field computed using eqn (16) with the electron probability density and the susceptibility tensor obtained from a DFT calculation. (D) Stereo plot of electron spin density isosurface (at the isovalues of ± 0.0004) in the complex. In all cases, the molecular geometry was optimized and the electron spin density estimated using DFT UB3LYP method^{25,26} in vacuum with cc-pVTZ basis set²⁷ on light atoms and Stuttgart ECP basis set on europium.²⁸ CSGT DFT UB3LYP²⁹ method with the same combination of basis sets was used to estimate the magnetic susceptibility tensor. Simulation source code is available within the example set of *Spinach* library version 1.5 and later.¹⁴

ligand field of the C_4 -symmetric N_8 cyclen ligand, and it is mostly the contact shift that is making PCS interpretation difficult.

Inverse problems

The most interesting possibility offered by eqn (16) and (17) is model-free recovery of the electron probability density distribution $\rho(\vec{r})$ and the susceptibility tensor χ from nuclear coordinates and pseudocontact shifts, in particular, for spin label conformation analysis in DEER experiments. The problem may be formulated as a minimization condition, with respect to $\vec{\rho} = \text{vec}[\rho(\vec{r})]$ and χ , for the following regularized least squares error functional:

$$\Omega(\vec{\rho}) = \|\mathbf{P}\mathbf{L}^{-1}\mathbf{K}\vec{\rho} - \vec{\sigma}_{\text{expt}}\|^2 + \lambda_1 \langle \vec{\rho} | \ln(\vec{\rho}) \rangle + \lambda_2 \|\mathbf{L}\vec{\rho}\|^2$$

$$\mathbf{K}\vec{\rho} = -(1/3)\text{vec}[\text{Tr}(\mathbf{H}_\rho \cdot \chi)] \quad (22)$$

where \mathbf{P} is the matrix that projects out pseudocontact shifts at nuclear locations, $\vec{\sigma}_{\text{expt}}$ is a vector of experimental PCS data and $\lambda_{1,2}$ are Tikhonov regularization parameters.¹⁵ The uncommon choice of regularization operators (maximum entropy and minimum Laplacian norm) is dictated by two practical considerations:

1. Electron probability distribution is expected to be localized in at least one dimension – even extended conjugated systems, such as porphyrin and carotene radicals, have electron spin densities that closely follow the bonding network. Maximum entropy regularization is known to favour local solutions unencumbered by baseline noise,¹⁶ hence the presence of $\lambda_1 \langle \vec{\rho} | \ln(\vec{\rho}) \rangle$ term in eqn (22).
2. Electron probability distribution is not infinitely sharp – some penalty should be placed that enforces a measure of broadening. Because electron spin densities often have symmetric distributions in PCS systems, high multipoles should also be discouraged in the solution. Both objectives are accomplished by $\lambda_2 \|\mathbf{L}\vec{\rho}\|^2$ term in eqn (22).

$\Omega(\vec{\rho})$ is non-linear with respect to $\vec{\rho}$, necessitating the use of numerical minimization methods (the memory-conserving version of the quasi-Newton method proposed by Broyden, Fletcher, Goldfarb and Shanno¹⁷ is used here), but good initial guesses may be obtained by noting that, for $\lambda_1 = 0$, the global minimum of $\Omega(\vec{\rho})$ with respect to $\vec{\rho}$ is analytical:

$$\vec{\rho}_{\text{min}} = (\mathbf{A}^T \mathbf{A} + \lambda_2 \mathbf{L}^T \mathbf{L})^{-1} \mathbf{A}^T \vec{\sigma}_{\text{expt}},$$

$$\mathbf{A} = \mathbf{P}\mathbf{L}^{-1}\mathbf{K} \quad (23)$$

A synthetic example of computing the PCS field generated by multiple paramagnetic centres and then recovering their distribution from PCS data is given in Fig. 2. Additional constraints on the probability density are non-negativity, fixed integral and zero boundary conditions:

$$\rho(\vec{r}) \geq 0; \quad \int \rho(\vec{r}) d^3\vec{r} = N; \quad \rho(\infty) = \rho'(\infty) = 0 \quad (24)$$

where N is the number of unpaired electrons in the system. Because the error functional in eqn (22) has two regularization

Fig. 2 An example of the inverse problem solution where the electron probability distribution is recovered from PCS data. (A) Volumetric stereo plot of a model system with three electrons with a randomly assigned susceptibility tensor and Gaussian probability distributions randomly positioned within a $20 \times 20 \times 20$ Å cube. (B) Volumetric stereo plot of the PCS field obtained from the probability density cube shown in (A) using eqn (21). (C) Volumetric stereo plot of the electron probability distribution obtained by solving the inverse problem as described in the main text. Pseudocontact shift was sampled at 500 random points emulating nuclear locations within the volume and fed into eqn (22), which was then minimized from a random initial guess. Simulation source code is available within the example set of *Spinach* library version 1.5 and later.¹⁴

parameters, a generalization of the L -curve method¹⁸ to surfaces¹⁹ is used here. Better regularization methods for eqn (16) that could improve the fidelity of the reconstruction in Fig. 2C are undoubtedly possible, but are beyond the scope of the present work.

Conclusions

Eqn (16) and (17) provide a simple and numerically friendly alternative to voluminous and abstruse multipolar expansions in situations where electron probability distributions deviate significantly from the point electron case. Both forward (PCS from $\rho(\vec{r})$ and χ) and backward (χ and $\rho(\vec{r})$ from PCS) calculations are straightforward – the former is accomplished in a single sparse matrix-inverse-times-vector operation prescribed

by eqn (21) and the latter is an instance of Tikhonov regularization of the well-researched source recovery problem for an elliptic PDE²⁰ with the error functional specified in eqn (22).

Attention should also be drawn again to the simple general connection between hyperfine shift and hyperfine coupling provided by eqn (10) – modern electronic structure theory packages are able to compute both hyperfine tensors and magnetic susceptibility tensors, meaning that hyperfine shift may be obtained essentially for free after standard magnetic property runs in ADF,²¹ ORCA²² or Gaussian,²³ subject only to the electron spin relaxation time being sufficiently short for the approximation made in eqn (3) to be valid.

The source code for all examples provided above, as well as numerical infrastructure functions (3D finite difference operators, 3D interpolation operators, Tikhonov solvers, volumetric scalar field visualizer, etc.), are available in versions 1.5 and later of *Spinach* library.¹⁴
