Ultrafast intersystem crossing dynamics in uracil unravelled by ab initio molecular dynamics†

Martin Richter, Sebastian Mai, Philipp Marquetand* and Leticia González

Ab initio molecular dynamics simulations have been performed in order to investigate the relaxation dynamics of uracil after UV excitation in gas phase. Intersystem crossing (ISC) has been included for the first time into time-dependent simulations of uracil, allowing the system to relax in the singlet as well as in the triplet states. The results show a qualitatively different picture than similar simulations that include singlet states only. The inclusion of ISC effectively quenches the relaxation to the singlet ground state and instead privileges transitions from the low-lying ππ* state (S1) to a ππ* triplet state (T2) followed by rapid internal conversion to the lowest triplet state.

1 Introduction

The interaction of ultraviolet (UV) light with deoxyribonucleic and ribonucleic acid (DNA/RNA) can lead to molecular photodamage and ultimately to mutations in the genetic code.1 Despite this possibility, DNA and RNA, as well as their building blocks – the nucleobases – are remarkably photostable. This means that, after light irradiation the excited molecules activate photophysical mechanisms that efficiently return the system to the electronic ground state before detrimental excited-state reactions can take place. The quest to understand how these molecules transform the absorbed energy into heat, redistributing it as kinetic energy among all the degrees of freedom and dissipating it into the environment avoiding damage, has become a hot topic.2–6 Accordingly, the last decade has witnessed a large number of experimental and theoretical studies on this subject.

Ultrafast time-resolved femtosecond (fs) spectroscopic studies7–22 have shown that the relaxation of nucleobases is not a single molecular process but rather a complex one, consisting of several subprocesses, which take place on different time scales. Although the specifics depend on the experimental setup, usually one subprocess is found to correspond to a time constant on the order of fs accompanied by another one on the time scale of a few picoseconds (ps); in some cases, longer subprocesses on the order of nanoseconds (ns) can also be detected.

With the help of extended theoretical methods, it seems now well-established that the observed ultrafast time scales responsible for photostability are the result of decay due to internal conversion (IC) via conical intersections (CInf), which are able to bring the excited molecule from the manifold of electronically excited singlet states to the ground state in a ps or sub-ps time scale.23–26 Less clear, however, is the role played by intersystem crossing (ISC) in the photodeactivation of nucleobases.

Static quantum chemical computations have proposed that ISC from the singlet to the triplet manifold should be possible in some of the nucleobases.27–33 The direct observation of triplet states is experimentally difficult if their quantum yield is small.34,35 Moreover, the standard pump–probe setups employed7,19–21 do not use a probe wavelength that can detect low-lying triplet states after excitation;36 therefore, the presence of triplet states is in most cases inferred indirectly. This has not prevented, however, to correlate triplet states to the long-lived transients observed experimentally. Despite the fact that spin–orbit couplings (SOC) are small in organic molecules and thus ISC is traditionally conceived as a slow process in comparison to IC,37 recently our group has demonstrated that, in cytosine, ISC can take place on an ultrafast time scale of a few hundreds of fs, hence also contributing to the fs and ps time constants detected experimentally.26,36,38 While ISC is astonishingly fast in this case, cytosine seems to be not the only organic molecule where ISC and IC processes can compete on the same time scale. Experimental fast to ultrafast times scales for ISC have been reported for aldehydes,39 a number of small aromatic compounds, such as benzene,40,41 naphthalene, anthracene and their carbonylic derivatives42–55 as well as nitrocompounds.46,56–68 The substitution of oxygen by sulfur in nucleobases enhances ISC so dramatically that the ultrafast IC responsible for photostability disappears while turning ISC to the lowest triplet states into the most efficient deactivation pathway – with enormous consequences for photodamage.64–66,69–74 The dimerization of...
pyrimidine nucleobases, one of the most abundant lesions in UV-irradiated DNA, is also claimed to be mediated by triplet states.\textsuperscript{35,75,76}

ISC is clearly an important photophysical process; however, dynamical simulations accounting for spin transitions are very much underrepresented in comparison to studies dealing with IC. Spin-induced transitions have been simulated by wave packet propagations along one or few dimensions by Daniel and coworkers in organometallic compounds.\textsuperscript{77-87} Several approaches, from quantum dynamics in reduced dimensions to semiclassical dynamics, have been combined to model and control the ultrafast spin–flip in dihalogens in argon matrices.\textsuperscript{88-91}

Surface-hopping methods have been also employed to study ISC in the S + H\textsubscript{2} reaction.\textsuperscript{92} However, the modelling of dynamical processes including both IC and ISC on the same footing is much more recent, especially in full dimensions. The dynamics of coupled singlet and triplet states have been simulated with a reduced vibronic Hamiltonian for benzene,\textsuperscript{41} HSe\textsuperscript{93} and with exact three-dimensional wave packets\textsuperscript{94} as well as with \textit{ab initio} molecular dynamics\textsuperscript{95} for SO\textsubscript{2}. Further semiclassical surface-hopping approaches using semiempirical Hamiltonians have been employed for acetone,\textsuperscript{96} pentanal\textsuperscript{55} and 6-thioguanine,\textsuperscript{70} using time-dependent density functional theory for a few transition metal complexes,\textsuperscript{97,98} and using on-the-fly \textit{ab initio} multi-configurational calculations for the DNA nucleobase cytosine.\textsuperscript{36,38}

In this work, we focus on uracil, an RNA nucleobase. Time-resolved experiments in uracil have been first reported in ref. 16 and later on by others.\textsuperscript{12,13,15} Depending on the resolution, one, two, or three time constants have been resolved. The most recent experiments of Kotur \textit{et al.}\textsuperscript{12} and Matsika \textit{et al.}\textsuperscript{13} combine time-of-flight mass spectroscopy (TOF-MS) with strong field dissociative ionization, thereby yielding a picture of multiple bifurcations in the deactivation mechanism of uracil. There have been a number of dynamical simulations published dealing with uracil,\textsuperscript{24,99-105} but none includes triplet states. Hence, the present study is designed to fill this gap, showing for the first time dynamics simulations including simultaneously non-adiabatic couplings (which mediate IC via CoIn) and SOC (which allows for ISC). We demonstrate that ISC competes with IC and should be taken into account to explain the ultrafast deactivation of uracil after UV irradiation. Further, the simulations presented in this paper aim at completing the knowledge on the fundamental question of which factors on the atomistic level contribute to the photostability of DNA/RNA, ultimately motivating experiments that can time-resolve non-adiabatic dynamics involving triplet states using emerging ultrafast photon technologies.

2 Methods

The molecular dynamics simulations on uracil have been carried out using the semiclassical \textit{ab initio} molecular code SHARC,\textsuperscript{106} which is a surface-hopping algorithm\textsuperscript{107} able to deal with arbitrary couplings. Previous dynamical applications of SHARC can be found in ref. 36, 38, 95 and 108–111. This surface-hopping algorithm uses a fully diagonal, spin-mixed electronic basis, resulting from the diagonalization of the Hamiltonian containing non-adiabatic and spin–orbit couplings.\textsuperscript{36,106} The integration of the nuclear motion is done with the velocity-Verlet algorithm\textsuperscript{112,113} with a time step of 0.5 fs for 1 ps; the time evolution of the quantum amplitudes is followed with a time step of 0.02 fs. Decoherence correction was taken into account using the energy-based method of Granucci and Persico with a parameter of $\gamma = \theta$ hartree.\textsuperscript{114}

The electronic energies, gradients, non-adiabatic couplings and SOCs were evaluated on-the-fly for each nuclear integration time step using the complete active space self-consistent field (CASSCF)\textsuperscript{115,116} method and the 6-31G* basis set. Two different active spaces were employed: a (12,9) consisting of 12 electrons in 9 orbitals and a (14,10), with two electrons more in an additional orbital. The latter active space consists of 8 $\pi/\pi'$ orbitals as well as 2 $n$ orbitals located at the oxygen atoms of uracil (see Fig. 1), and it has been employed before for quantum chemical calculations\textsuperscript{117} and molecular dynamics in the singlet manifold only.\textsuperscript{104,105} The smaller active space contains one oxygen lone pair less. The excited state properties are calculated using the state-average CASSCF version, including the lowest four singlet states and the lowest three triplet states, \textit{i.e.}, 7 electronic states. Note that in the dynamics the triplet components were treated explicitly, giving 13 states in total. The assessment of the CASSCF energies has been done using single point calculations at the more accurate CASPT2\textsuperscript{118,119} level of theory. All quantum mechanical calculations were performed using the MOLPRO 2012 package of programs.\textsuperscript{120}

For the generation of the initial conditions, the ground state equilibrium geometry was optimized at the CASSCF(14,10) or CASSCF(12,9) level of theory, as specified below. Using the corresponding harmonic frequencies, a Wigner distribution of 2000 uncorrelated velocities and geometries has been generated. For each initial condition a single point calculation has been performed to simulate an absorption spectrum from the oscillator strengths, as explained in ref. 121. The oscillator strengths also serve for selecting the number of trajectories to be propagated from each electronic excited state, assuming an instantaneous excitation (a $\delta$-pulse).

The evaluation of trajectories is made only on those finishing the whole simulation time of 1 ps, unless specified otherwise, or
residing in the $S_0$ or $T_1$ for at least 15 fs. For the statistical evaluation, we calculated so-called “spectroscopic” populations in addition to the ones in the molecular Coulomb Hamiltonian (MCH) electronic basis. The transformation from the MCH basis to the spectroscopic one is done in an approximate manner using the transition dipole moment between the electronic ground and the calculated excited states. If the transition dipole moment is greater than 0.05 a.u., the state is considered a bright $\pi\pi^*$ state and for values less than 0.05 a.u. the state is a dark $\pi\pi^*$ state. If the transition dipole moment is very small (< 1 x 10^-6 a.u.) the state is assigned to a triplet state. The ground state $S_0$ corresponds always to the closed-shell state in the present case and therefore, we use the label $S_0$ also in the spectroscopic representation. Statistical analysis of the trajectory data within the spectroscopic representation provides a better description of the experimentally observed decay rates, since the physical properties of the spectroscopic states change less than in the MCH representation.\(^{36}\)

3 Results and discussion

3.1 Excitation energies and absorption spectrum

The pyrimidine nucleobase uracil presents 13 different tautomers. Among them, this study focuses on the diketo form (Fig. 2) since it is the biologically relevant and the dominant tautomer in gas phase and solution.\(^{123}\)

![Fig. 2 Uracil in its diketo form, with ring atom numbering.](image)

The experimental absorption spectrum of uracil shows its maximum at 244 nm (5.08 eV).\(^{124}\) A number of excited state calculations for uracil are reported in the literature. For all CASPT2 calculations, the band at ca. 5.1 eV corresponds to the $S_2$ state, which is of $\pi\pi^*$ character and possesses the largest oscillator strength. The lowest-lying singlet state is of $\pi\pi^*$ character and its energy fits reasonably well within the energetic range recorded experimentally.\(^{125}\) Taking as a reference the calculation of Climent et al.,\(^{29}\) who use CASPT2/CASSCF(14,10) and averaging separately singlet (SA4) and triplet (SA3) states, one can see that the nature of the $S_1$ state is more sensible to the level of theory. Using this SA4/S3-CASPT2/CASSCF(14,10) protocol, the first excited dark $\pi\pi^*$ state is followed by two $\pi\pi^*$ states, whereas a SA7-calculation (where singlet and triplets states are averaged together) predicts a second $\pi\pi^*$ state as the $S_2$. The removal of one n-orbital (the $n_{O2}$) from the active space (resulting in an (12,9) active space) yields the same order of states as in Climent et al.\(^{29}\) The use of symmetry to obtain the $A'$ and $A''$ states separately, as done in the benchmark paper of Schreiber et al.,\(^{125}\) has a minor effect in the CASPT2 energies. The inclusion of dynamical correlation when going from CASSCF to CASPT2, in contrast, is more important, since it affects the singlet $\pi\pi^*$ states more dramatically than the $\pi\pi^*$ ones, thereby influencing greatly the energetic position of the singlet states in uracil. While $S_1$ and $S_2$ are almost degenerated at CASPT2, the destabilization of the $\pi\pi^*$ at CASSCF separates the states by more than 1 eV, making in turn the $S_2$ and $S_3$ very close in energy. The triplet states seem to be more robust with respect to the level of theory, both regarding the active space and the inclusion of dynamical correlation. The $T_1$ is a $\pi\pi^*$ state located at around 4 eV, well-separated energetically from an $n\pi^*$ and a second $\pi\pi^*$ state.

The critical analysis above illustrates that the choice of the level of theory for the dynamics can be very important, as the state energies are expected to influence the time evolution of the system and determine the population of the states. Particularly the energy gaps govern, together with the couplings, the hopping probabilities to other singlet states or to the triplet states, and therefore it seems natural to think that different levels of theory could deliver different results, distorting the interpretation of the experiments. Ideally, one would like to employ CASPT2 for the on-the-fly calculations since it is one of the most reliable ab initio methods in this case. Due to unfavorable scaling of CASPT2, we are limited to use CASSCF instead. Nevertheless, to assess the impact of the active space on the dynamics, the two active spaces ((14,10) and (12,9)) have

\(^{a}\) Climent et al.,\(^{29}\)\(^b\) For $\pi\pi^*$: SA5($A'$)-CASPT2(10,8)/6-31G*, for $\pi\pi^*$: SA4($A'$)-CASPT2(14,10)/6-31G* from Schreiber et al.,\(^{125}\)\(^c\) Masaaki Fujii and Ito.\(^{128}\)\(^d\) Clark et al.,\(^{124}\)
been employed for the subsequent SHARC molecular dynamics calculations. The \((14,10)\) active space has previously been used in the dynamical simulations of Fingerhut et al.\(^{104,105}\) including singlets. The \((12,9)\) active space is chosen since it predicts the same order of the states as CASPT2.\(^{29,125,129}\)

Using the 2000 uncorrelated geometries of the Wigner distribution, an absorption spectrum was calculated from the oscillator strengths and excitation energies. Fig. 3 shows the absorption spectrum calculated with both active spaces. As it can be seen, the system is initially excited to the \(S_2\) and \(S_3\) states. Both states are bright as a direct result of the distribution of the initial geometries around the equilibrium geometry. Even if the \(S_3\) is a dark \(\pi\pi^*\) at the ground state equilibrium geometry using the \((14,10)\) active space, a small geometrical displacement can alter the order of state characters, especially when both states are energetically close. Thus, \(S_3\) takes \(\pi\pi^*\) character and hosts a significant amount of excited population. As a result, irrespective of the initial character of the states, both \(S_2\) and \(S_3\) contribute to the absorption spectrum obtained with CASSCF. The relative distribution of population in the \(S_2\) and \(S_3\) states depends, however, on the active space; specifically, the \(S_2\) state dominates the spectrum in the energy region explored in our simulations with the \((12,9)\) active space. Globally, the lack of dynamic correlation in the CASSCF method shifts this band towards higher excitation energies. Accordingly, the maximum dynamic correlation in the CASSCF method shifts this band towards higher excitation energies. Hence, to investigate the influence of the excitation energy on the excited state dynamics of uracil, Ensemble III was prepared from 64 trajectories, distributed as 37 and 27 in \(S_2\) and \(S_3\), respectively, resembling the distribution of states within the energy window of 0.14 eV centered around 6.59 eV. Finally, the influence of the active space is evaluated from the simulations of Ensemble IV, which comprises 40 trajectories, where CASSCF\((12,9)\) was used in the dynamics instead of CASSCF\((14,10)\). Energies were chosen to cover the full range of the theoretical absorption spectrum. From these trajectories, 28 and 12 were initially excited to the \(S_2\) and \(S_3\) states, respectively, and propagated for 500 fs.

Based on the obtained absorption spectra, four sets of trajectories were prepared (see Table 2). Ensemble I was taken as a reference set to assess the impact of ISC. Accordingly, only IC within the singlet states was allowed and any possible ISC towards the triplet states was neglected. This set contained 49 trajectories prepared at the CASSCF\((14,10)\) level of theory, from which 26 and 23 were excited to the \(S_2\) and \(S_3\) states, respectively, according to the associated oscillator strengths. The trajectories were selected as to cover the full excitation range and were propagated during 600 fs. Ensemble II was composed of 120 trajectories from the CASSCF\((14,10)\) initial conditions, also covering the full spectrum, and were split in 64 and 56 over the states \(S_2\) and \(S_3\). Since experimental setups do not cover the full spectrum but use a laser pulse of fixed wavelength, a third set of trajectories (Ensemble III) was prepared to match the energy range accessed experimentally. Gas phase pump–probe experiments in uracil\(^{12–14}\) typically employ a wavelength of 267 nm (4.64 eV) and pulse widths around 50 fs, resulting in an energy bandwidth of \(\pm 0.07\) eV. Accordingly, the experimental excitation wavelength is about 0.44 eV below the observed absorption maximum of 224 nm (5.08 eV). Hence, to investigate the influence of the excitation energy on the excited state dynamics of uracil, Ensemble III was prepared from 64 trajectories, distributed as 37 and 27 in \(S_2\) and \(S_3\), respectively, resembling the distribution of states within the energy window of 0.14 eV centered around 6.59 eV. Finally, the influence of the active space is evaluated from the simulations of Ensemble IV, which comprises 40 trajectories, where CASSCF\((12,9)\) was used in the dynamics instead of CASSCF\((14,10)\). Energies were chosen to cover the full range of the theoretical absorption spectrum. From these trajectories, 28 and 12 were initially excited to the \(S_2\) and \(S_3\) states, respectively, and propagated for 500 fs.

#### 3.2 Excited state dynamics including singlet states only

A number of gas phase excited-state dynamical studies including only singlet states are available for uracil. In Fig. 4 we have sketched the mechanisms derived from these studies. Using CASSCF\((8,6)\) wavefunctions and full multiple spawning (FMS), Hudock et al.\(^{99}\) found in 2007 that after excitation uracil gets trapped in the \(S_2\) minimum (see Fig. 4a). One year later, Nieber, Doltsinis and coworkers\(^{100,101}\) employed surface-hopping trajectories coupled to Car–Parrinello dynamics on potentials calculated with the ROKS/BLYP approach and observed a sub-ps direct decay from the \(\pi\pi^*\) state to the ground state, governed by the so-called ethylenic \(\pi\pi^*\text{/}S_0\) CoIn (see Fig. 4b and also Section 3.4). The semiempirical-based OM2/MRCI simulations of Lan et al.\(^{102}\) obtained two different relaxation mechanisms, as depicted in Fig. 4c. The first path directly connects the bright \(\pi\pi^*\) state with the \(S_0\) ground state via the ethylenic CoIn, while the second, slower pathway, connects the initially excited \(\pi\pi^*\) state with the \(\pi\pi^*\) state via a planar \(S_3\) CoIn that is located close to the Franck–Condon region. The trajectories spend some time in the \(\pi\pi^*\) state until finally reaching the \(S_0\) via a different \(S_3\) CoIn.
CASSCF(14,10) wavefunctions that describe four singlet states. ref. 24 and 103 argue that the efficiency of the direct analoguous dynamics would be expected. The authors of published by Fingerhut and coworkers 104,105 and are based on state relaxation, affecting the time scales obtained.

Note that the one-dimensional cartoons imply different reaction coordinates.

The surface-hopping simulations at the CASSCF(10,8) level of theory of Barbatti et al.24 and by Nachtigallova et al.,103 showed that three deactivation pathways (which involve three electronic states) are possible – see Fig. 4d. The first one is equivalent to that suggested before in ref. 99–101: after initial trapping in the S2 minimum, the trajectories go to the S0 via a \( \pi^* \)/S0 CoIn. Interestingly, this path is not observed in a comparable study made on thymine,130 even though thymine and uracil have very similar potential energy surfaces and analogous dynamics would be expected. The authors of ref. 24 and 103 argue that the efficiency of the direct \( \pi^* \to S_0 \) path in thymine is significantly reduced due to the heavy mass of the methyl group. The second pathway found in uracil is also not observed in thymine and involves a crossing with the \( \pi^* \) state. The implicated CoIn, termed ring-opening CoIn, leads to the destabilization of the ground state as the ring breaks. At these geometries the \( S_1 \) wavefunction contains contributions of \( \sigma \) orbitals and therefore it is described as a \( \sigma(n-\pi)^* \) state. In their work, it is also noted that this pathway would probably lead to photochemical products different from the equilibrium geometry. Interestingly Buschhaus et al.131 do observe ring opening after UV irradiation of nucleosides but the detected isocyanates (R–N=C=O) cannot arise directly from the N1-C4 bond cleavage predicted by Nachtigallova et al.103

The third deactivation pathway involves a change of character to \( \pi^* \) after initial trapping and relaxation through the \( S_2/S_1 \) CoIn. The trapping in the \( \pi^* \) minimum delays the ground state relaxation, affecting the time scales obtained.

The most recent surface-hopping simulations have been published by Fingerhut and coworkers104,105 and are based on CASSCF(14,10) wavefunctions that describe four singlet states. After initial excitation a fast decay of the \( S_3 \) population is observed [not shown in Fig. 4c], together with a slower decrease of \( S_2 \) population and an increase of \( S_1 \) population that exceeded the \( S_2 \) population after about 400 fs of simulation time, in agreement with the two mechanisms of Lan et al.102

In the first pathway, the initially populated \( S_2 \) state of \( \pi\pi^* \) character decays to the \( S_0(n\pi^*) \) state, gaining more than 20% of population in less than 100 fs. In the \( \pi\pi^* \) state, population can be trapped before decaying to the \( S_0 \), leading to long relaxation times. Interestingly, this study shows much less pronounced trapping in the \( S_2 \) state than the one of Nachtigallova et al.,103 even though both studies use CASSCF. Fingerhut et al.104 attribute the difference to the size of the active space size. The second pathway involves a transition to \( S_1 \) without changing the state character (i.e. staying in the \( \pi\pi^* \) state), followed by \( \pi\pi^* \to S_0 \) relaxation through the ethylenic CoIn. In their simulations, all trajectories that reached the ground state within 1 ps followed the second pathway and only a few trajectories relaxed via the first pathway in longer runs of up to 2 ps.

All the previous simulations can be compared with the results obtained using the Ensemble I of trajectories. Fig. 5 shows the time evolution of the different state populations. Not surprisingly, our results are comparable to that of Fingerhut et al.104 because they are made at a similar level of theory. In essence, the \( S_2(\pi\pi^*) \) state decays to the \( S_0(n\pi^*) \) and repopulation of the ground state occurs within 100 fs. As it will be shown in the next section, the inclusion of triplet states changes this picture dramatically.

### 3.3 Excited state dynamics including singlet and triplet states

Fig. 6a shows the time-evolution of the singlet and triplet state populations of the trajectories considered in the Ensemble II (recall Table 2). Although the propagations are made in the basis of fully diagonal, spin-mixed states, the analysis is carried out in the MCH and spectroscopic representations in order to be able to compare to previous studies.

As in the singlet-only case (Ensemble I), the trajectories initially excited to the \( S_3 \) state show a very efficient decay to \( S_2 \). Therefore, after 200 fs the \( S_3 \) is completely depopulated and

---

**Fig. 4** Schematic overview of the proposed deactivation mechanisms of uracil, from ref. 99 (a), ref. 100 (b), ref. 102, 104 and 105 (c), and ref. 103 (d). Note that the one-dimensional cartoons imply different reaction coordinates.

**Fig. 5** Time evolution of the population of electronic states, including only singlet states (Ensemble I).
whereas the $S_1$ accumulates up to 15% and other higher excited states are mostly populated via IC to the $S_1$. However, after 1 ps still 50% of the excited singlet population in the $S_2$ state, which within the first 40 ps collects about 75% of the total population, remains. In similitude to the singlet-only case (Fig. 5). During the rest of the propagation time, the population of the $S_2$ state decreases slowly due to IC to the $S_1$. However, after 1 ps still 50% of the excited trajectories are trapped in the $S_2$, indicating that the population resides in the surrounding of the $S_2$ minimum. The rest of the population is transferred to the $S_1$, which gains some population in the beginning from $S_3$ and later on slowly via $S_2 \rightarrow S_1$ transitions, but not as substantially as in Fig. 5. From the $S_1$, some trajectories decay to the $S_0$ within the first 200 fs via the so-called ring opening CoIn (see Fig. 10c in the next section). Only after this time, the $S_0$ population starts increasing very slowly, unlike in the singlet-only case. The reason is obviously that there is a significant amount of population accumulated in the triplet states after the total propagated time. With 22%, the $T_1$ state has the largest population, after the $S_2$ with 50%, whereas the $S_1$ accumulates up to 15% and other higher excited states ($S_3, T_2, T_3$) show only populations below 3%. The $T_1$ state is mostly populated via $S_1 \rightarrow T_2$ ISC, followed by very efficient $T_2 \rightarrow T_1$ IC. This qualitative distribution of populations is fundamentally different from the case where only transitions within the singlet manifold are allowed ( Ensemble I shown in Fig. 5) because an additional channel (ISC) has been opened to compete dynamically with IC.

Neglecting the possibility of ISC in the simulations results in a strong increase of $n\pi^*/S_1$ population. Thus, the population of the singlet $n\pi^*$ state exceeds the population of the $\pi\pi^*/S_2$ state after about 400 fs (Fig. 5). This population inversion is not observed in the simulations that allow for population of the triplet states via ISC (Fig. 6a). Here, the depopulation of $S_1$ due to ISC processes prevents the population inversion of the excited singlet states as well as the efficient population of the $S_0$ ground state within 1 ps. Thus, our simulations suggest that ISC processes in uracil are too slow to compete with IC of the excited singlet states in the early times, but can significantly alter the fate of the population trapped in the lowest excited singlet state. As a result, IC to the ground state and ISC to the triplet manifold are in direct concurrence. A general decay scheme summarising the processes discussed above is given in Fig. 7a.

The majority of the $S_1 \rightarrow T_2$ transitions follow El-Sayed’s rule, \(112,113\) i.e. the transitions involve a change of state character in the singlet–triplet transition. Usually the $S_1$ is of $n\pi^*$ character and the $T_2$ is of $\pi\pi^*$ character (see ESI† on how to evaluate the state character), resulting in large SOCs that peak above 60 cm\(^{-1}\) (39 cm\(^{-1}\) on average). The energy difference of the involved states at the ISC geometries is very small, 0.01 eV (98 cm\(^{-1}\)) on average, favouring the process of ISC.\(^{31}\)

Restricting the allowed excitation energy range to 6.59 ± 0.07 eV ( Ensemble III) yields qualitatively similar results, see Fig. 8. However, the energetic restriction leads to a smaller triplet yield and a concomitantly slightly larger population in the ground state. This behaviour results from the smaller total energy of the trajectories which reduces the probability to reach geometries that allow for efficient ISC, giving the system more time to relax via $S_i/S_0$ CoIns to the electronic ground state.

For a more detailed comparison of the dynamical simulations with the experiment, it is useful to follow the time evolution not of the MCH states ($S_0, S_1,$ etc.) but of the spectroscopic states, i.e. the states classified according to their character ($n\pi^*, \pi\pi^*$, etc.).\(^{112}\) Indeed, time-dependent experiments do not monitor occupations in states ordered by energy, but follow the change of physical properties, such as oscillator strengths or ionization yields, that heavily depend on the character of the states. Therefore, we show the spectroscopic populations in Fig. 6b for Ensemble II (the results for Ensemble III are qualitatively very similar). The comparison between both representations (panels a and b) shows a strong correlation of the $S_2$
state with the $\pi\pi^*$ character and the $S_1$ with $\pi\pi^*$. Initially, all trajectories start in a bright $\pi\pi^*$ state that corresponds to $S_2$ and $S_3$, recall Fig. 3a. The decay of the $S_3$ population to the $S_2$ in the MCH picture hence corresponds to vibrational relaxation in the bright $\pi\pi^*$ state. A sketch in Fig. 7b illustrates this pathway, where the $\pi\pi^*$ state is indicated as solid, light blue curve. Along this path, IC to the dark $\pi\pi^*$ state (indicated as solid, dark blue curve) can occur. This $\pi\pi^*$ state mostly corresponds to the $S_1$ state in the MCH representation. A branching can lead further to the ring-opening discussed above ($\pi(\sigma\pi)\pi^*$, solid yellow).

As was shown before in Fig. 3 and Table 1, a change of the active space of a CASSCF calculation leads to a change of the potential energy surfaces, which might lead to different dynamics. The impact of the active space onto the relaxation dynamics has been investigated with the dynamical simulations of Ensemble IV. Fig. 9 shows an overlay of the electronic state populations of Ensembles II (CASSCF(14,10)) and IV (CASSCF(12,9)) within the first 500 fs after $\delta$-pulse excitation. Obviously, the initial populations mirror the Wigner distribution of geometries, so that Ensemble IV shows a higher population of $S_2$ in the first 200 fs. Also the initial relaxation from $S_2$ to $S_1$ is slower in Ensemble IV, as a result of the increased energy gap between those states at the CASSCF(12,9) level of theory in comparison to CASSCF(14,10) energies (see Table 1). After 200 fs, however, the differences between the electronic state populations are not substantial, suggesting that qualitatively the effect of the active space is not dramatic in this case. The differences in the approximate spectroscopic states (not shown) are even smaller, showing that the results are robust with respect to different active spaces with different state ordering at the Franck–Condon geometry (see Table 1).

### 3.4 Conical intersections and hopping structures

It is well-known that the population transfer in molecular dynamics simulations does not exactly happen at the minimum energy points of the seams of CoIns.\textsuperscript{134} One can, however, relate the hopping geometries with the CoIns that can be optimized by means of static quantum chemical calculations. To this aim, all the hopping geometries where IC between singlets and IC between triplets occurred have been used as a starting point of a state crossing optimization. Some of the obtained geometries correspond to previously reported geometries, others are new crossing points which have been discovered by the dynamics. Fig. 10 collects all the geometries optimized in this work as well as exemplary geometries that illustrate frequently observed features of ISC transitions.

Fig. 10a corresponds to a $\pi\pi^*/\pi\pi^*$ CoIn that allows for $S_2/S_1$ hops. This structure has been previously found by Mercáñ \textit{et al.}\textsuperscript{135} and Lan \textit{et al.}\textsuperscript{102} and predicted at 5.92 eV above the equilibrium ground state energy at CASSCF level of theory. In our calculations, this structure is higher in energy (6.38 eV) due to the larger number of averaged states. One hop from $S_2$ and $S_1$ was found mediated by a different structure, depicted in Fig. 10b, which is characterized by a twist of the ethylenic HC–CH group and a strong out-of-plane distortion of the aromatic ring. As already stated by Lan \textit{et al.},\textsuperscript{102} this reduction of planarity lowers the energy, in this case by 0.13 eV (CASSCF). However, precisely due to the strong distortion it is unlikely for many trajectories to proceed to this specific region of the...
potential energy surface (as corroborated by the present simulations where only one hop was found facilitated by this structure).

In the deactivation from $S_1$ to $S_0$, two geometries have been located. The most frequently used by uracil is the ring opening CoIn depicted in Fig. 10c where the aromatic ring of the system is opened to maintain the planarity. The second CoIn, shown in Fig. 10d, involves a twist of the ethylenic bond and it is therefore often referred to as the ethylenic $S_1/S_0$ CoIn. This latter structure was observed only in 3 hopping events. Both CoIns have been also reported by Nachtigallova et al. Thus, it can be concluded that the deactivation to the ground state within the first 200 fs is mediated by the ring opening CoIn and later deactivation happens via the ethylenic CoIn. These two mechanisms contribute to explain the biexponential increase behaviour that can be observed when fitting the populations of the $S_0$ and $T_1$ (vide infra).

ISC is mainly mediated by $S_1 \rightarrow T_2$ transitions. Several structures could be obtained where these states come close in energy (<1 meV). These structures are dominated by heavy changes of the C–O bond lengths (Fig. 10e) or ring puckering (Fig. 10f). Ring deformations, such as the reduction of the N1–C2 bond length to only 1.22 Å can also lead to degeneracy between both states (Fig. 10g).

In contrast to the $S_1 \rightarrow T_2$ transitions, $S_1 \rightarrow T_1$ ISC occurs rarely and only one hopping structure has been found where both states are energetically close to each other ($\Delta E < 0.1$ eV). This structure, see Fig. 10h, is characterized by a strongly elongated C4–O bond (1.70 Å) and a deformed aromatic ring with a short C5–C6 bond (1.27 Å) and a long C4–C5 bond (1.55 Å).

IC between the $T_2$ and $T_1$ states is facilitated by two different geometries that are about 4.11 and 4.38 eV above the ground state equilibrium energy at CASSCF level of theory. The geometry lower in energy shows an out-of-plane displacement of the oxygen at C4 by about 21°. The C4–O bond is elongated to about 1.37 Å, whereas the C2–O bond is shortened to 1.20 Å (Fig. 10i). This structure is very similar to the one described by Climent et al. using quantum chemical calculations. The other CoIn lies 0.3 eV higher and shows the oxygen at C2 sticking out of the ring plane by about 54° and the C2–O bond elongated to 1.41 Å (Fig. 10j).

3.5 Decay times

Uracil has been subject of a number of time-dependent experimental studies, whose reported time constants and experimental setups are collected in Table 3. The first pump–probe experiments in gas phase in uracil were made by Kang et al. Using a pump pulse of 267 nm excitation and multi-photon ($n \times 800$ nm) ionization as a probe, a monoexponential decay of the ionization signal yield with a time constant of 2.4 ps was fitted. Using higher time resolution, later studies were able to find an additional ultrashort time constant between 50 and 130 fs. Interestingly, except for the time-resolved photoelectron spectra of Ullrich and coworkers, recorded with a 250 nm excitation and a 200 nm probe pulse, who fitted a 3-exponential decay (<50 fs, 530 fs, 2.4 ps), most experiments find a biexponential decay behaviour after photoexcitation. In 2005, Canuel et al. observed a decay of the transient ionization signal with time constants of 130 fs and 1.1 ps and the fluorescence upconversion experiments of Gustavsson et al. recorded
Table 3  Decay times of uracil as measured by pump–probe experiments in gas phase or solution (denoted by”) or calculated theoretically using different methods, as indicated. The symbol X indicates that the relevant paper discusses that timescale without giving a quantitative time constant. Numbers in parentheses in the third block refer to Ensemble III (see text)

Fluorescence upconversion in aqueous solution.

an ultrafast decay of fluorescence in aqueous solution with a time constant of less than 100 fs. Recent experiments of Kotur et al.²⁰ and Matsika et al.²¹ combine TOF-MS with strong field ionization (n × 780 nm) to obtain insight into the differences between the dynamics of different uracil fragments and the parent ion. In all their studies, they report a biexponential decay with a short time constant of 70–90 fs and a long time constant in the picosecond region (2.2–3.2 ps).

The time constants reported in previous theoretical studies are also listed in Table 3. Curiously, most theoretical studies have obtained mono- or biexponential decays, where the time constants have mostly been assigned to the intermediate transient observed by Ullrich et al.²⁵ Early FMS investigations of uracil by Hudock et al.²¹ at the SA-CASSCF(8,6) level of theory report only small yields for IC within the first 500 fs after starting in the bright S₂ state. They claimed the experimentally observed ultrafast time constant (\( \tau_1 \)) to be the result of the system’s initial vibrational relaxation towards the S₀ minimum, hand-in-hand with a significant increase of the ionization potential. In contrast to this, the Car–Parrinello molecular dynamics studies of Nieber et al.¹⁰⁰ and Doltsinis et al.¹⁰¹ employing the BLYP functional, observe a single time constant of 608 fs for the S₁ → S₀ deactivation at 300 K that decreases to 551 fs at 0 K temperature. The semiempirical surface-hopping simulations of Lan et al.¹⁰² describe a biexponential decay with time constants of 21 and 530 fs, attributing the fast component to the S₀ → S₁ transitions and the slow component to the relaxation from S₁ to S₀. The \textit{ab initio} surface-hopping simulations reported by Barbatti et al.²⁴ and Nachtgallova et al.¹º also find a biexponential decay. Depending on the initial energy of the trajectories, to match a 250 nm or 267 nm excitation, they arrive at time constants of 650 fs and >1.5 ps or 740 fs and >1.8 ps, respectively. The faster of the two time constants is attributed to a relaxation to the ground state by either \( \pi\pi^*\rightarrow\pi\pi^* \) decay via an opening of the aromatic ring, leading to a mixed \( \sigma(n-\pi)\pi^* \) character of the excited state when the transition to the ground state occurs. The longer time constant is attributed to the trapping of the trajectories in the dark \( \pi\pi^* \) state before they relax to the ground state. In the recent study of Fingerhut et al.¹⁰³ explicit lifetimes are not given, but a fast S₂(\( \pi\pi^*\rightarrow\pi\pi^* \)) decay is observed as well, leading to a population of more than 20% of the initially dark S₂(\( \pi\pi^*\)) state after less than 100 fs. In this state, the trajectories get trapped before they slowly proceed towards the S₀ ground state. A second study of Fingerhut et al.¹⁰⁴ using a larger ensemble of trajectories allowed them to extract a time constant of 516 fs for the depopulation of the bright S₂(\( \pi\pi^*\)) state.

The third block of Table 3 collects time scales fitted in this work from Ensemble II, values from Ensemble III are given in parentheses. As a prerequisite for fitting time constants that are comparable to experimental results, the neutral states leading to the experimental signal need to be identified. In case of an ionization setup, states with an ionization potential larger than the multiphoton ionization energy (\( i.e. \) states of the neutral molecule much lower in energy than the ground state of the ion) are assumed as dark, while all other states...
exhibit different brightnesses. It is often assumed that only the $S_0$ ground state is dark in these studies and the decay constant fits are based on this state’s population. However, it has been shown for cytosine, that additionally the lowest triplet state ($T_1$), may be dark for the probe pulses typically employed in the experiments. Since cytosine and uracil are structurally very similar and the quantum yield of $S_0$ obtained in our simulations is low, fitting was performed over the sum of $S_0$ and $T_1$ population, analogously to cytosine. Note that fitting ought to be carried out in the spectroscopic representation, but in our case, the $S_0$ coincides with the spectroscopic closed-shell state. Moreover, triplets cannot be distinguished in our way of determining the spectroscopic states, but we should include only the lowest triplet state in the fit. Thus, it is justified exceptionally to perform this part of the analysis using the $S_0$ and $T_1$ population. Fitting of the $S_0$ and $T_1$ population of Ensemble II with a biexponential function yields two time constants of 63 fs and 2.8 ps.

The fs time constant stems from an early relaxation of population to $S_0$ and $T_1$ via the ring-opening Coln (see Fig. 10c). However, static calculations at higher level of theory predict a strong destabilization of the ring-opening Coln and this pathway might actually be blocked. Therefore, a monoexponential fit was performed in addition, which yields a lifetime of 2.4 ps in good agreement with the experimentally observed ps time constant. Note however that any time constants in the range of several picoseconds have to be taken with a grain of salt since the simulation time was restricted to 1 ps. Also, the errors given in Table 3 represent the asymptotic standard errors of the fitting procedure alone and do not take into account further errors introduced by other approximations included in the simulation. Therefore, they do not represent errors with respect to real, experimentally measurable decay times. The mechanism behind the ps time constant involves several processes. Population relaxes from the $\pi\pi^*$ to the $\pi^*$ state via the Colns shown in Fig. 10a and b. From the $\pi^*$ state, ISC leads mostly to the triplet $T_2$ state of $\pi^*$ character in this region (exemplary structures are shown in Fig. 10c–h) followed by ultrafast IC to the lowest triplet state $T_1$ ($\pi\pi^*$ in this region). Population in the $\pi\pi^*$ that does not deactivate via ISC, can reach the $S_0$ ground state via the Colns shown in Fig. 10c and d. Since the monoexponential fit describes the population decay well, it can be followed that ISC and ground state relaxation occur on comparable timescales.

So far, only the decay to states that are assumed completely dark has been considered in the fitting procedure. However, the experimental signal may be also changed by transitions to states where the brightness is different from the state occupied before but non-zero. This is the case in uracil for the transition from the $\pi\pi^*$ to the $\pi^*$ state. The $\pi^*$ state is quickly depopulated during the first few fs and afterwards the decay slows down considerably. Consequently, the depopulation of the $\pi\pi^*$ state was fitted biexponentially, yielding a time constant of 30 fs for the initial $\pi\pi^*$ to $\pi^*$ decay. This relaxation proceeds via the Colns shown in Fig. 10a and b, as already discussed for the ps time constant. However, the pathway here is slightly different. Initially, population is excited to the $\pi\pi^*$ state in the Franck–Condon region. From there, the ensemble of trajectories moves almost coherently towards the potential minimum of the $\pi\pi^*$ state and a fraction relaxes via $S_0$ to the $\pi^*$. Especially the planar structure shown in Fig. 10a is similar to the equilibrium structure of ground state uracil and therefore easily accessible from the Franck–Condon region. This fast decay of the bright $\pi^*$ state population is also in qualitative agreement with the fast decay of fluorescence in the experiments of Gustavsson et al. in solution. The trajectories remaining in the $\pi\pi^*$ state proceed towards the $\pi^*$ minimum and only at later times the trajectories can move back to the $\pi\pi^*/\pi^*$ Colns. Since this return requires then a motion up in potential energy, the process is slowed down, leading to a time constant of 3.2 ps. This constant is very similar to the one for the decay to $S_0$ and $T_1$, but slightly slower. Hence, the $\pi^*$ state is slower replenished than depopulated, leading to a slight decay of its population.

Restricting the excitation energy to a small window below the absorption maximum (Ensemble III) increases the lifetimes of the monoeXponential fit of $S_0$ and $T_1$ population to 4.2 ps and for the biexponential fit to 48 fs and 5.2 ps in agreement with the results of Nachtigallova et al. The biexponential decay of $\pi\pi^*$ population in Ensemble III yields time constants of 8 fs and 2.6 ps. The first constant is even faster than in Ensemble II and hence also below the time resolution of the discussed experimental studies. The second constant is shortened as well and is now faster than the $S_0 + T_1$ time constant in the ps regime. As a consequence, the population of the $\pi^*$ state remains more or less constant after an initial steep rise. This behaviour is in line with a summation of the seemingly different time constants of 8 fs, 2.6 ps ($\pi\pi^*$ depopulation) and 4.2 ps ($S_0 + T_1$ population). Note however that a multitude of different processes underly the found time constants including electronic transitions through various Colns, vibrational relaxation and ISC. To find the connection between experimental time constants and the underlying physical processes is hence extremely challenging without the help of theoretical predictions. For a detailed discussion of the fitting functions used to obtain the presented time constants, the interested reader is referred to the ESL.

Interestingly, we do not find the intermediate time constant that was reported experimentally only once in ref. 15 and could not be reproduced in later experimental studies. Theoretical studies assign this time constant to different processes, ranging from the $S_0$ population obtained from DFT and CASSCF studies with small active spaces to the depopulation of the bright $S_0/\pi\pi^*$ state obtained using CASSCF with larger active spaces. Thus, the origin of this time constant remains unclear.

Generally, the existence of an ultrafast time constant below 100 fs and a long time constant of several ps is in agreement with recent experimental studies (see Table 3). The short time constant is somewhat smaller than experiments suggest, what could be a result of the limited experimental time resolution and the theoretically employed $\delta$-pulse excitation. The long
time constant however is in excellent agreement with experimental results, confirming the validity of our findings.

4 Conclusions

In summary, this study provides clear evidence that intersystem crossing should be considered in any time-dependent treatment of the relaxation processes in uracil. Whereas time-independent quantum chemical computations can provide important intermediate structures of the potential energy surfaces, like conical intersections, minima and transition states, time-dependent dynamical studies are mandatory to evaluate the impact of these structures on the actual relaxation mechanism. As shown in this study, the exclusion of possible interactions between states of different multiplicity can qualitatively change the photophysical picture of the processes taking place.

Our dynamical calculations including both non-adiabatic and spin–orbit couplings show that the deactivation mechanism of uracil after UV light irradiation is the result of several competing processes. After 1 ps a significant fraction of the population can be found in the S\(_2\), which mainly corresponds to the \(\pi\pi^*\) state. The relaxation process can be characterized by a biexponential decay. A fast component \(\tau_1\) (30 fs) is attributed to the change of state character from the initially excited \(\pi\pi^*\). The slower constant \(\tau_2\) (2.4 ps) arises from intersystem crossing in direct competition to internal conversion. The S\(_1\) state, which is of \(\pi\pi^*\) character, was found to be the doorway to triplet states, since population is trapped there for a sufficiently long time to allow intersystem crossing. In contrast to previous studies,\(^{104,105}\) only a very small amount of population returns to the ground state within 1 ps because ground state relaxation is quenched by intersystem crossing. The ground state relaxation is mediated by the ethylenic CoIn and the ring-opening path previously observed by Nachtigallova et al.\(^{103}\)

The direct comparison of the decay lifetimes to those experimentally detected yields very good agreement and therefore supports the conclusion, that intersystem crossing from the first excited singlet state is in direct concurrence to internal conversion towards the ground state of uracil. Solvent effects could affect the observed time scales and the relative quantum yields of the involved processes. Therefore, the particular influence of solvation on intersystem crossing should be investigated in the future.

References

the outcome of theoretical chemistry is usually given in terms of the eigenfunctions of the non-relativistic electronic Hamiltonian (= molecular Coulomb Hamiltonian, MCH). Here, the electronic states of a given multiplicity are ordered and labelled with respect to their energy, e.g. \( S_0, S_1, \ldots \) (in case of singlets). States strictly ordered by energy can never cross and the corresponding representation is thus sometimes called ‘adiabatic’ (greek: not passing through). However, if more than one multiplicity of states is considered, the term ‘adiabatic’ is not appropriate anymore. In order to avoid this confusion, we employ the term ‘MCH representation’. It is important not to confuse the different labels, since e.g. if relaxation pathways are discussed, the representation matters. Exemplarily, a pathway in terms of the spectroscopic representation may start in a \( \pi\pi^* \) state and from there relax directly to the closed-shell state. The same pathway in the MCH representation could start in \( S_2 \), from there lead to \( S_1 \), and then relax to \( S_0 \). In this example, we are faced with the situation that the \( \pi\pi^* \) state corresponds to the \( S_2 \) state at some geometries and to the \( S_1 \) state at others. Such considerations also play a role when establishing a model to fit decay time constants. However, a conversion between the different representations is not straightforward and great care needs to be taken in all photorelaxation studies, when comparing theory and experiment.
