Impact of high $\pi$-density on the coordination properties of $\pi$-excess aromatic neutral $\sigma^2P$ ligands – P(\pi)-donor bonds to Ag\(^+\) and HgCl\(_2\)\(^+\)

Mohammed Ghalib,\(^a\) László Könczöl,\(^b\) László Nyulászi,\(^*b\) Peter G. Jones,\(^*c\) Gottfried J. Palm,\(^d\) and Joachim W. Heinicke\(^a\)

Unprecedented coordination types of non-zerovalent d\(^{10}\) transition metals (AgX, HgCl\(_2\)) by $\pi$-excess aromatic P=\(\pi\) ligands involving P(\pi)-donor bond contributions were detected by structural and quantum chemical studies.

Trivalent phosphorus compounds are widely used ligands in coordination chemistry and homogenous late transition metal catalysis, but studies on ligands with dicoordinated ($\sigma^2P$) phosphorus are restricted almost completely to phosphabenzynes\(^1\) and some phosphaalkenes.\(^2\) Complexes with $\pi$-excess-aromatic $\sigma^2P$-azaphosphole ligands, apart from metal(0) complexes,\(^3,4\) are extremely sparsely documented,\(^5,6\) and only one, a 1,2-aza-phosphole allylnickel chloride complex,\(^6\) has been characterized by crystal structure analysis. Complexes of the $\pi$-rich 1,3-azaphospholes with phosphorus in conjugation to nitrogen (N=C=P $\leftrightarrow$ N'C=P') are still unknown for non-zerovalent transition metals. We report here the first examples with d\(^{10}\) metal cations; these 1,3-benzazaphosphole Ag(i) and HgCl\(_2\) complexes display a hitherto unprecedented coordination pattern. Structurally characterized $\sigma^2P$-Ag(i) complexes are very rare,\(^7,8\) and we are not aware of any Hg(II) complexes with $\sigma^2P$-ligands.

Addition of toluene and NH\(_3\) to an equimolar mixture of 1\(^9\) and AgCl at $\sim$60 °C and warming to r.t. led to the formation of an inversion-symmetric benzazaphosphole silver chloride complex with a central Ag\(_2\)Cl\(_2\) ring (Scheme 1). Colourless crystals of 2 were obtained on overlaying a concentrated solution in THF with hexane. The crystal structure analysis (Fig. 1) displays distorted tetrahedral coordination of Ag\(^+\) with an interplanar angle of 80.8° between the Ag,Cl\(_2\) and the P3–Ag–P3' planes. The P–Ag bonds do not lie within the extended ligand ring plane, but are tilted away by 32.4 and 12.7°. The bond

\(^*\)Electronic supplementary information (ESI) available: Syntheses and NMR spectra of 2, 3, and 5, crystallographic details for 2 and 5 and quantum chemical calculations. CCDC 926714 and 926715. For ESI and crystallographic data in CIF or other electronic format see DOI: 10.1039/c3dt52909f
lengths and angles within the ligand are only marginally changed (P-C3a slightly shortened) compared to 1. A cationic silver complex of a different coordination type was formed in THF at room temperature from a mixture of 1 and AgSbF₆. Crystals of 3 were grown by slow concentration of a solution of the pale brown crude product in CD₃OD. They proved to be less stable than 2 and decomposed within a few days, but crystallographic analysis of freshly prepared crystals of 3 clearly revealed two [Ag(1)₄THF₄(SbF₆)₃]⁺⁺ clusters with μ-P coordination and four uncoordinated SbF₆⁻ counter-ions per unit cell (in space group P2₁/c). Full refinement was not possible, with the THF molecules and SbF₆⁻ ions being disordered (for details see ESI†). The sharp singlets lacking coupling with ¹⁰⁷/¹⁰⁹Ag in the CD₃OD solution of silver complexes 2 and 3 indicate a rapid ligand exchange and thus kinetic lability. Complex formation is indicated mainly by upfield coordinated ³¹P chemical shifts, much stronger for the μ-P bridged 3 (Δδ = −76.7 ppm) than the terminally coordinated 2 (Δδ = −18.9 ppm). Characteristic features in the ¹³C NMR spectra are decreasing ¹/Jₚc coupling constants of C2 and C3a and downfield shifts of the C-2 signals, whereas proton NMR data are scarcely altered.

To find out if divalent mercury is also able to form complexes with 1,3-benzazaphospholes, the reaction of 1 with HgCl₂ in THF was explored. Oxidation of phosphorus to a λ³P heterocycle as reported for the reaction of 2,4,6-triphenylphosphabenzene with Hg(OAc)₂ was not observed. The NMR spectra of the yellow solid, with a marked upfield ³¹P coordination chemical shift in C₆D₆ (Δδ = −84.8 ppm), indicated complex formation, but attempts to grow single crystals for a detailed structural characterization failed. A crystalline 1,3-benzazaphosphopho-HgCl₂ complex was finally obtained from the recently reported ⁴⁻P-hybrid benzazaphosphole ⁴¹ and HgCl₂ in THF (Scheme 2). XRD analysis of the yellow single crystals of 5 (Fig. 2), grown from concentrated THF solution, showed a P,P'-chelate structure as expected. However, whereas in the recently reported Mo[0](CO)₄(P,P')-chelate complex with 4 the zero-valent metal is only slightly (by 14.4°) tilted out of the ring plane with shorter ring-P-Mo than Ph₃P-Mo(0) distances and marginal changes within the ligand, the HgCl₂ complex 5 coordinates mercury almost perpendicular to the benzazaphosphole ring plane with much longer Hg-P₃ (2.6978(7) Å) than Hg-P₁ bonds (2.4219(5) Å) and altered P–C and C–N bond lengths within the ring. The angle of the Hg-P vector to the ring plane of 80.3° (deviation from plane 2.62 Å) and the angles C₂-P–Hg (86.40(8)) and C₃a-P–Hg (98.92(8)), average

Fig. 2 Structure of 5 in the crystal (ellipsoids with 50% probability).

92.7°, hint at a π-donor bond from the ring-P atom to Hg(II). In combination with the elongated C₂–P and shortened N–C₂ bond (1.770(3) Å) and 1.344(3) Å compared to 1.7173(17) and 1.369(2) Å in the Mo(0) complex this implies a high weight for a zwitterionic P-coordinated phosphidomethyleniminum "resonance structure" (cf. Scheme 2). The increased NH acidity favours N–H⋯Cl hydrogen bonds (H01⋯Cl(2)#1 2.42(3), N1⋯Cl(2)#1 3.238(2) Å, N–H⋯Cl 169(3)°) in the crystal packing and in solution, the latter indicated by a strongly downfield shifted NH proton signal (Δδ = 3.0 ppm). The coordination of HgCl₂ at the two P-atoms is indicated in solution by a downfield shift for the phosphanyl group Δδ = 31.0 ppm, similar to that of (Ph₃P)₂HgCl₂ (Δδ = 39 ppm) for Ag, and upfield shift for the ring-P atom, which is however much smaller than for the μ-bridging coordination in 3 and even smaller than for the two terminal benzazaphosphole ligands in 2. The coordination at the ring-P atom is labile, displaying a rather sharp doublet by two-bond P-P-coupling but no ¹/J(¹¹²Hg/¹³⁵P) satellites, whereas the coordinated phosphanyl group exhibits a broad signal associated with the dynamic behaviour at the other P-atom.

The coordination of two benzazaphosphole ligands at each Ag(i) atom, the tilting of the P–Ag bond out of the ring plane in 2, the μ-coordination mode in 3 and the unprecedented side-on coordination in the chelate complex 5 distinguish the complexes of the π-excess-type P=C–N ligands 1 and 4 from phosphabenzene complexes, which usually coordinate non-zero-valent transition metals within the ring plane. To shed light on the background of these differences and to understand the unusual bonding in more detail, density functional calculations were carried out at the ωB97D/6-31G* level. First a second order perturbation analysis of the donor-acceptor interaction between NBOs at the crystal structures of 2 and 5 was performed. While in the case of 2 both P lone pairs at each atom exhibit about 60.5 kcal mol⁻¹ stabilization donating to Ag, an additional 6.4 kcal mol⁻¹ stabilization interaction was obtained for the (P=C bond)–Ag interaction in the case of the 32.4° tilted azaphosphole ring, showing some donor contribution of the σ electron pair to the dative bonding. In the case of 5 the interaction between the σ-P lone pair and mercury amounts to 129.0 kcal mol⁻¹, while the interaction
between the σ²P and mercury is only 12.1 kcal mol⁻¹. The small interaction with the mainly s-type σ²P lone pair is in agreement with the near perpendicular position of the Hg atom with respect to the benzazaphosphole ring. The apparently lost (P lone pair)–Hg interaction, however, is amply compensated by the 40.0 kcal mol⁻¹ stabilization arising from the interaction between the P=parity orbital and mercury. This interaction is also clearly seen on the HOMO of 5 with the involvement of both Hg and the mainly P=parity delocalised π orbital (the HOMO of the benzazaphosphole ligand) as is shown in Fig. 3.

The involvement of the (largely) P=parity bonded orbital in the dative bonding is in agreement with the lengthening of the P=distance (see above). It is noteworthy that no back-bonding from P to π* type orbitals was observed. Optimization of the structure of 5 at the ωB97D/6-31G* level resulted in a shift of the Hg atom from phosphorus towards the ring nitrogen, together with the formation of an intramolecular C–H bond (see Fig. S3.3 in the ESI†). This behaviour is in agreement with the conclusions drawn from the solution NMR data discussed above. To understand why mercury prefers to interact with the P= bond rather than the P lone pair, further model calculations were carried out. In order to exclude the effect of any steric constraint caused by the interlocking of the two phosphorus atoms of 4, the structure of various L(PMe₃)HgCl₂ complexes was investigated, where L contained σ²P in different bonding environments.

During the geometry optimization of the benzazaphosphole the HgCl₂ unit occupies an out-of-plane position similar to that in 5 (albeit with larger P–Hg distances), even if the geometry optimization is started from a structure where Hg lies in the plane of the benzazaphosphole ring. The complexes with the other ligands exhibit similar structural characteristics, with the exception of the in-plane complexed phosphabenzene ligand. The optimized structures can be seen in Fig. S3.4 of the ESI†. It is noteworthy that the σ²P–Hg distance (between 2.57 and 3.49 Å) is related to the interaction energy between the π-system and mercury. Strongest interactions are obtained with ligands (L) having high energy (and localised) HOMO (Table 1) as can easily be explained by simple perturbation theory arguments.

Accordingly, while the phosphabenzene ligand with stabilised P=parity orbitals (in agreement with the aromaticity) has a limited π-interaction and thus prefers the “classical” n_p → Hg bonding, the electron-rich P=parity units (high energy HOMO) prefer the π interaction. The aromatic stabilization on the P=parity orbital of the 1,3-azaphosphole (compared to the 1,3-azaphospholene), together with the delocalization, weakens the interaction with mercury. It should be noted that a phenyl mercury compound with intermolecular phenyl Hg π-interactions is known, however, its linear geometry is not distorted by the weak interaction.

In conclusion, we have presented the first complexes of π-rich σ²P-aromatic 1,3-azaphosphole ligands with non-zero-valent late transition metals and revealed unprecedented significant π-donor contributions in the coordinative bond. Our findings suggest to search for related P(π) donor complexes which open up new tuning possibilities in the highly important field of phosphorus-based late-transition metal catalysis.

*a D_π_→_Hg^*; *b n_p → Hg. c n_p → Hg.

13 Density functional calculations (see details in the ESI†) were carried out at the ωB97D/6-31G* level (for Hg and Ag the pseudopotential defined for the def2-ccPVTZ basis was applied) using the Gaussian 09 suite of programs. M. J. Frisch *et al.*, *Gaussian 09, Revision B.01*, Gaussian, Inc., Wallingford, CT, 2010.

15 Since the Cl⋯HN interaction modifies the geometry, we used the N-methylated benzazaphosphole as L.

16 It has been shown that the stabilization of the lone pair orbital energies – as judged from the corresponding measured ionization energies compared to the saturated counterpart – in five membered heterocycles is related to the aromaticity. L. Nyulászi, Gy. Keglevich and L. D. Quin, *J. Org. Chem.*, 1996, **61**, 7808. This is because of the favourable HOMO–LUMO interaction between the fragments in the case of the cyclic conjugated compounds.
