Evolution of disposable bamboo chopsticks into uniform carbon fibers: a smart strategy to fabricate sustainable anodes for Li-ion batteries†

Jian Jiang,‡[a] Jianhui Zhu,‡[a] Wei Ai,[a] Zhanxi Fan,[b] Xiaonan Shen,[a] Chenji Zou,[a] Jinping Liu,[d] Hua Zhang[b] and Ting Yu*[ac]

Future development of mini consumer electronics or large electric vehicles/power grids requires Li-ion batteries (LIBs) with not only an outstanding energy-storage performance but also a minimum cost, and the foremost sustainability. Herein, we put forward a smart strategy to convert used disposable bamboo chopsticks into uniform carbon fibers for anodes of LIBs. Bamboo chopsticks waste is recycled and simply treated by a controllable hydrothermal process performed in alkaline solutions, wherein abundant natural cellulose fibers in bamboo *in situ* get separated and dispersed spontaneously. After carbonization, the evolved carbon fibers exhibit superior anodic performance to the bulky bamboo carbons counterpart, and competitive electrochemical behavior and cost with commercial graphite. The performance of carbon fibers can be further upgraded by growing nanostructured metal oxides (like MnO_2) firmly on each fiber scaffold to form a synergetic core–shell electrode architecture. A high reversible capacity of ~710 mA h g^{-1} is maintained without decay up to 300 cycles. Our strategy presents a scalable route to transform chopsticks waste into carbon fibers, offering a very promising way to make sustainable anodes for LIBs and economical multi-functional carbon-based hybrids available for other practical applications.

Broader context

Li-ion batteries (LIBs) nowadays play a dominant role on the progress of HEVs/EVs industry. However, despite the ceaseless development of electrode materials selection/manufacturing, current LIBs still show little promise in competing with the traditional gasoline in terms of price, energy, convenience and safety. Besides, the excepted huge exploitation on graphite driven by future demands will eventually one day lead to the depletion of natural graphitic resources. In a long-term perspective, LIBs therefore require to not only possess outstanding energy-storage capability but also be lower-cost and foremost sustainable. We herein propose a smart strategy to convert the used bamboo chopsticks into uniform carbon fibers for a sustainable anode of LIBs. Abundant natural fibers in chopsticks waste are readily separated and dispersed after a simple hydrothermal treatment. The derived carbon fibers exhibit superior anodic performance as compared to the bulky counterparts, and competitive electrochemical behavior and cost with commercial graphite. Moreover, their performance can be further upgraded by integrating nanostructured metal oxides onto each fiber. Our success in the evolution of carbon fibers from chopsticks waste may provide a cost-effective and sustainable platform for developing advanced carbon-based materials for practical use, not merely in LIBs but also in a wide spectrum of fields.

1. Introduction

The ever-increasing market penetration of hybrid electric or all-electric vehicles (HEVs or EVs) requires not only a continual improvement of the battery performance (particularly on fast charges output/storage) but also minimization of the battery cost as much as possible. Li-ion batteries (LIBs) based on the classic electrochemical system of carbonaceous anode and Li salts cathode (*e.g.*, layered $Li_{1-x}MO_2$, olivine $LiMPO_4$ and spinel $Li_{1-x}M_2O_4$, wherein M represents the transition metal) are superior to nickel–metal hydride batteries (Ni–MH) or ambient-temperature fuel cells on the market.[1–3] They play a predominant role in the progress of HEVs/EVs industry owing to their attributes of high energy density, good rate performance, reliable stability and long lifespan.[2] Despite the ceaseless

development of LIBs technology on electrode materials selection/manufacturing, the purchase cost of HEVs/EVs (mainly spent on LIBs units and related accessories) is yet far higher than that of the mainstream gasoline-powered automobiles. Up to date, the current LIBs still show little promise of offering safe and sufficient capacity, with acceptable lifetime, good convenience and affordable price to compete with traditional fossil fuels.[4] In addition, the majority of commercially used anodic graphite stems from mineral deposits. Similar to the petroleum case in history, the prospective huge exploitation on graphite driven by future demands in EVs and large electricity grids would one day lead to the depletion of graphitic resources. The successful and large-scale commercial popularization of HEVs/EVs, in a longer-term perspective, ought to rely on the advent of renewable, environmentally benign and cheaper electrode materials that still have a satisfactory electrochemical performance, preferably close to an infinite abundance in nature.[5]

The use of chopsticks brings about the mysterious verve of East Asia's catering culture but inevitably results in negative environmental impact and enormous waste of precious forest resources. Only in Japan, humans stupendously consume around a total of ~24 billion pairs of disposable chopsticks per year (adding up to millions of cubic meters of timber or fully grown bamboo trees).[6] This giant consumption gives rise to a great many issues, in which the overriding concern is how to appropriately deal with the vast of discarded chopsticks garbage. Current handling approaches are still the conventional ones realized by either direct combustion of these wastes or sanitary landfills for biodegradation. Even though treatments in such ways are rather simple and convenient, they are virtually "low-level" and not rational, causing extra air/dust pollution and, more importantly, making little use of these valuable and economic natural resources. How humans process the large amount of disposable chopsticks waste into commercially available products through general, high-efficiency and cost-effective approaches is quite desirable but still needs serious reconsidering.

We herein put forward a scalable and smart strategy to convert disposable bamboo chopsticks waste into uniform carbon fibers for LIBs application. The recycled bamboo chopsticks only undergo a simple and controllable hydrothermal (delignification) treatment conducted in alkaline solutions, in which plenty of cellulose fibers in bamboo are *in situ* separated and dispersed spontaneously. Both the reaction time and alkali concentration are verified as significant parameters to adjust the overall fiber-separation process. Extracted natural fibers are further evolved into graphitic carbon fibers after a carbonization treatment. When tested as anode for LIBs, the chopsticks-derived carbon fibers can exhibit competitive anodic performance with practical graphitic materials, and much better electrochemical behavior than unseparated bamboo carbon in terms of specific energy and rate capability. We also find the anodic performance of carbon fibers can be markedly upgraded by integrating nanostructured metal oxides (*e.g.*, MnO_2) onto each carbon fiber. Thanks to the three-dimensional (3D) functionalized core–shell constructions, the hybrid products of C/MnO_2 NWs/carbon fibers have been demonstrated as

excellent anode materials for LIBs, with good cyclic performance (maintaining ~710 mA h g^{-1} without decay up to 300 cycles) and outstanding rate capability. To our knowledge, their comprehensive anodic performance is among the best reported to date for the hybrid systems of MnO_2@carbon matrix. Our success in the evolution of carbon fibers from chopsticks waste may not only open up the possibility of manufacturing sustainable high-performance anode materials for LIBs, but also set up an economical platform for preparing advanced hierarchical carbon-based hybrid materials that might be available in a large spectrum of practical applications.

2. Experimental

2.1 Synthesis of carbon fibers

The disposable bamboo chopsticks were used as raw materials and recycled from the canteens of Nanyang Technological University (NTU). The cleaned bamboo chopsticks were initially processed into bamboo shavings (length: ~1.4 cm; width: ~0.2 cm; thickness: ~0.06 cm) using a penknife. Within the underlying hydrothermal treatment, 1 g of bamboo shavings were put into a Teflon-lined stainless steel autoclave wherein a 70 mL of homogeneous 3 M KOH solution was contained. Then, the autoclave was sealed and placed still in an electric oven at a temperature of 150 °C for 6 h. When cooled down to room temperature naturally, the samples were fetched out, collected by vacuum filtration with common filter paper, washed by ultrasonication in 150 mL distilled water just for one time and dried at 60 °C in an electric oven. Next, the cotton-like products were calcined at 800 °C under the protection of Ar flow (flow rate: 80 ppm) for 2 h, allowing for adequate carbonization of the bamboo fibers into carbon fibers. Last, the evolved carbon fibers are washed with 0.1 M HCl to remove the residual KOH and dried at 60 °C for 12 h.

2.2 Synthesis of C/MnO$_2$ NWs/carbon fibers

The hybrid of C/MnO_2@carbon fibers was prepared *via* simple hydrothermal treatment using carbon fibers as the raw materials. In details, a glass slide with 0.2 g of "cotton-like" carbon fibers fixed on, was put into a 100 mL Teflon-lined stainless steel autoclave containing 50 mL of 0.04 M $KMnO_4$ solution. The autoclave was then sealed and kept in an electric oven at 150 ± 0.1 °C for 6 h. Next, the hybrid samples were fetched from the glass slide and cleaned by ultrasonication treatment for a few seconds to remove MnO_2 nanoparticle debris. After that, the formed intermediates were soaked into 50 mL of 10 mmol glucose solution and kept still at 60 ± 0.1 °C for 12 h. Last, the samples were taken out, dried in air and calcined at 550 °C in Ar flow (80 sccm) for 1 h.

2.3 Material characterization

The crystalline structure and morphology of carbon fibers were characterized using a transmission electron microscope (high-resolution TEM/TEM, JEM 2100F) and a field-emission scanning electron microscope (FESEM, JEOL JSM-6700F). An X-ray powder diffraction (XRD) pattern was recorded by a Bruker D8

Energy Environ. Sci., 2014, **7**, 2670–2679 | **2671**

Advance diffractometer with Cu-Kα radiation ($\lambda = 0.15418$ nm). The mass of the electrode materials was precisely measured on a microbalance (A&D Company N92, Japan) with an accuracy of 0.01 mg. Nitrogen adsorption–desorption isotherms were measured at 77 K with a Micromeritics analyzer (Belsorp Mini). Thermogravimetric analysis (TGA) was performed on a SDT600 apparatus under a heating rate of ~10 K min^{-1} in air. X-Ray photoelectron spectroscopy (XPS) spectrum was measured on a Perkin-Elmer model PHI 5600 XPS system with a resolution of 0.3–0.5 eV from a monochromated aluminium anode X-ray source. The Raman spectrum was obtained using a Witech CRM200 Raman system with 532 nm excitation laser. Microscopy observations were conducted by a universal research microscope (OLYMPUS, BX51).

2.4 Electrochemical testing/characterization

The working electrodes were fabricated by a conventional slurry-coating method. For details, carbon fibers, poly(vinylidene fluoride) (PVDF) binder and Acetylene Black were mixed in a mass ratio of 80 : 10 : 10 and dispersed/homogenized in N-methyl-2-pyrrolidone (NMP) to form slurries. The homogenous slurry was then pasted onto a Cu foil (thickness: 10–15 μm) and dried at 100 °C for 10 h under vacuum. The mass loading of fiber products on each current collector was controlled to be 2.5–4.0 mg cm^{-2}. Electrochemical measurements were all performed using CR-2032 coin-type cells within a potential range of 0.005–3 V. The cells were assembled in an Ar-filled glove box (MBraun, Unilab; H_2O < 0.1 ppm, O_2 < 0.1 ppm) using Li foil as the counter and reference electrode. 1 M LiPF$_6$ dissolved in a 1 : 1 (v/v) mixture of ethylene carbonate (EC) and diethyl carbonate (DEC) was used as the electrolyte. Electrochemical impedance spectroscopy and cyclic voltammetry measurements were performed on an electrochemical workstation (CHI 760D, CH Instruments Inc., Shanghai) and galvanostatic charge–discharge tests were conducted using a specific battery tester (NEWARE, Shenzhen). Prior to battery testing, all cells were aged for 8 h.

3. Results and discussions

3.1 Characterizations of bamboo chopsticks

Bamboo usually acts as an all-purpose problem solver and suits a wide range of applications by virtue of its unique fibrous structure.[7] Bamboo chopsticks made of bamboo culms can be anatomically perceived as an aggregation of numerous oriented cellulose fibers embedded in an interwoven ligneous matrix (see the schematic in Fig. 1A). The tubular cellulose fibers (mass ratio: ~60%) have a biological function as nutrient/water transport corridors between the root and the leaves, whereas the part of lignin (mass ratio: 10%–20%), a sort of 3D highly cross-linked polyphenolic polymer,[8] plays the role of binding these fibers together. Microscopy observations on bamboo chopsticks are shown in Fig. 1B–D. Closer inspection toward their transverse section reveals that they distribute a large quantity of micro-sized fibers in bamboo, particularly around or near the vascular bundles. Scanning electron microscope (SEM) images

(Fig. 1E–H) also show appealing microstructures of these natural fibers, with a tubular diameter ranging from 5 to 10 μm. The fibrous structure seems preferable for energy storage applications like supercapacitors and LIBs because the tubular architecture itself can provide large inner surface areas and enrich the electrochemically active sites when compared to the solid counterpart.[9] Note that on the tubular wall of bamboo fibers there exist plenty of nanosized holes or cavities. These natural nanostructures that originally offer passages for biomass exchange between neighboring fibers are also favorable for energy storage, capable of supplying extra access to the inside of microtubes and thus shorten the distances for ionic diffusion. Nevertheless, it is unfortunate that bamboo fibers always bundle tightly with each other even after high-temperature carbonization or high-energy ball-milling treatments.[7] Though using techniques of boiling, soaking or mechanical extraction is helpful for the isolation of bamboo fibers, the yielded fiber products are rather rough.[10] Their diameters are usually centered at ~200 μm, signifying that at least hundreds of microfibers are still bundled together. Such bulky carbonized host materials are difficult to be completely permeated by the electrolyte. This is not beneficial for kinetic intercalation/deintercalation of Li$^+$. In an effort to tap the full potential of each fiber for LIBs, advanced techniques of fiber extraction/dispersion with good scalability are highly encouraged.

3.2 Carbon fibers evolved from bamboo chopsticks

We hereby develop a simple and effective way of evolving bamboo chopsticks into individual carbon fibers to address the fibers extraction/dispersion issue above and to enable each single carbon fiber applicable for Li storage. Fig. 2A displays the entire evolution procedures. Recycled bamboo chopsticks are firstly cleaned and made into shavings followed by a hydrothermal treatment performed in an alkaline solution for lignin removal. During the hydrothermal process, the lignin part between neighboring bamboo fibers gradually dissolves into the hot KOH solution. The trace for lignin removal/dissolution was captured using SEM observation (see Fig. S1†). We need to stress that the use of KOH would never be a critical issue for the scale up of our synthetic procedures since such treatments with alkali have been adopted in varieties of industrial productions, especially in paper and printing/dyeing industries. After lignin removal, the cotton-like cellulose fibers mixed with residual KOH are further calcined at 800 °C under the protection of Ar flow. Particularly noteworthy is that our produced carbon fibers still maintain good toughness (no visible changes appear even after a press of 10 pound weight; see Fig. S2†), unlike other fragile fibers made from cotton, silk or cobweb.[11] SEM and TEM observations (Fig. 2B–E and S3A†) illustrate the yielded fibrous products are uniformly dispersed, having a fluffy texture and a large aspect ratio of a magnitude of several hundreds or even thousands (the mean diameter of the single fiber is observed no more than 6 μm while its maximum length even reaches a few centimeters upward). This special "ultrahigh-aspect-ratio" property would potentially endow the anodic electrode with an outstanding high-rate performance by transferring electrons

directly along the long 1D electronic conducting cables rather than in disordered particle networks through numerous inter-particle contacts.[12] Another structural highlight is that on the carbon fiber surface there are homogeneously distributed mesoporous pores (10–20 nm in dimensions), which are quite accessible for the deep insertion of Li$^+$ into the whole fiber region. The generation of these mesopores results from the activation process by means of alkali (KOH) corrosion to carbon materials at a high temperature (6KOH + C → 2 K + 3H$_2$ + 2 K$_2$CO$_3$).[13] Fig. 2F shows the diameter distribution for a representative set of derived fiber samples. The fiber diameters are mainly varied from 2.4 to 6.4 μm with the highest distribution between 3.6 and 4.8 μm. In optimized states, we find that the minimum thickness of carbon fibers is even down to ∼600 nm (see Fig. S3B and C†). All these values are lower than that of pristine fibers (∼10 μm) in bamboo chopsticks, attributed to the volumetric contraction of cellulose fibers when bamboo chopsticks are successively subjected to delignification and carbonization treatment. The XRD pattern (Fig. 2G) and Raman spectrum (Fig. 2H) are also used to characterize the carbon fibers. The well-defined two diffraction peaks present in the XRD pattern correspond to (002) and (100) facets of hexagonal carbon (JCPDS no. 41-1487), respectively. Both diffraction peaks look broad since the graphite domain/crystalline size is extremely small, though specimens have been annealed at a temperature as high as 800 °C.[5a] According to the Scherrer equation, the mean domain thickness is calculated to be ∼1.85 nm from the full width at half-maximum values of (002) peak. This suggests that the graphitic domain is composed of 5–6 carbon layers (i.e., 1.85/0.34 = 5.44), matching well the result of HRTEM observation (Fig. S3D†). The Raman spectrum shows two fingerprint peaks, involving a disorder-induced D band (1341 cm^{-1}) and an in-plane vibrational G band (1592 cm^{-1}). The G band has a bit higher peak intensity than the D band (I_D/I_G ratio is ∼0.96), indicative of a higher degree of graphitization than the commercially used carbon cloth, carbon fiber papers or even carbon nanotubes in previous literature sources.[14] The X-ray photoelectron spectroscopy (XPS) measurement on a carbon fiber surface (Fig. S4†) discloses that there remain other elements like F (9.5%), O (6.5%) and Cl (1.0%). The as-formed functional groups (e.g., C–O, C=O, C–F, C–Cl, etc.) are quite useful since they may contribute part of the capacities via lithiation/delithiation or pseudocapacitive reactions. The N$_2$ adsorption–desorption isotherm with a hysteresis loop (inset in Fig. 2I) shows a typical "type I" characteristics (according to IUPAC recommendations) which is usually displayed by microporous solids especially for instances of carbon materials.[15] The specific surface area for evolved carbon fibers is measured around ∼808.25 m^2 g^{-1}. Also, we have calculated the micropore size of fiber specimens based on the density functional theory (DFT) (Fig. 2I). The carbon fibers contain ∼47% microporosity below 2 nm, with small mesopores centered among a range of 2–10 nm. The existence of such surface defects and hydrophilic function groups as above is very helpful for the nucleation formation of other functionalized active materials on the carbon surface.[16] This potentially enables the immobilization of high-capacity materials with robust

mechanical adhesion to carbon fibers scaffold, eventually forming advanced core–shell synergetic hybrid electrode systems for LIBs. Moreover, we have measured the electrical performance of a single carbon fiber (Fig. S5†). Its electrical resistivity is evaluated around ∼10^{-1} Ω cm (very close to that of metals), which is quite favorable for LIBs performance especially for high-rate lithiation/delithiation.

Seeking to control the entire preparation of bamboo fibers, we thereby carry out systematic studies on the relationships between KOH concentration (C_{KOH}) and other significant parameters like the hydrothermal reaction time and the weight losses of the chopsticks. Fig. 3A and B successively display their reaction time (t) and percentage loss in weight (wt%) as a function of C_{KOH} at a constant hydrothermal temperature of 150°. When C_{KOH} is as much as 1 M, t of 15 ± 2 h needs to be spent for the complete extraction of bamboo fibers. This treatment gives rise to a wt% up to ∼31.3%. Upon the increase of C_{KOH} from 1 to 6 M, t has to be 9 ± 1.5 h (for 2 M), 6 ± 0.5 h (for 3 M), 5 ± 0.3 h (for 4 M), 4.75 ± 0.25 h (for 5 M) and 4.5 ± 0.2 h (for 6 M), corresponding to the wt% of ∼28.3%, ∼22.7%, ∼23.3%, ∼26.7%, ∼33%, respectively. As reflected by the experimental data and their fitting analysis, the fiber-extraction procedure is proven to be highly associated with t and C_{KOH} parameters. Using a high molar-ratio alkali solution enables to shorten t by acceleration of the delignification process but in turn inevitably causes dissolution of the partial cellulose fibers (∼21% solubility percentage in concentrated alkaline) as well as the high wt%.[17] Though prolonging the hydrothermal time indeed eliminates the use of concentrated KOH solution, the corresponding wt% is not the lowest since a long hydrothermal period would also result in a partial weight loss of the biomass. Considering the manufacturing cost and production efficiency of bamboo fibers, we eventually choose 3 M KOH as the hydrothermal solution, along with a moderate t (6 h) and the lowest wt% (∼22.7%). Moreover, we also pay close attention to other influence factors, like reaction conditions, as compared and summarized in Table 1. Underneath the 5 h soaking treatment in either alkaline/acid solutions or neutral water, we fail to attain any cellulose fibers; there are actually no changes on bamboo chopsticks after the soaking process except for the ones soaking in alkaline aqueous solutions (with a slight weight loss of ∼3–6% caused by dissolution of the biomass in bamboo). As for events under hydrothermal conditions,

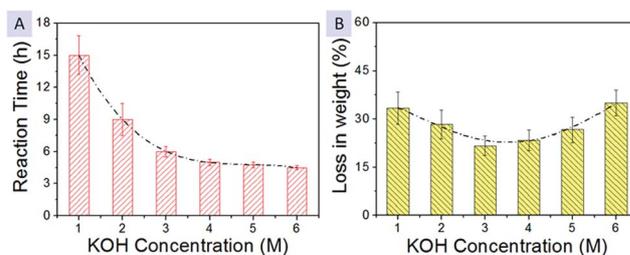

Fig. 3 Relationships between the KOH concentration (C_{KOH}) and other significant parameters of (A) hydrothermal reaction time (t) and (B) weight loss (wt%) of the chopsticks shavings.

Table 1 Comparison of bamboo fibers extraction performed by distinct chemical treatments

Treatment	Bamboo fibers extraction (yes/no)	Experimental results
Soaking in pure H_2O at room temperature (RT) for 5 h	No	No changes
Hydrothermal treatment (150°) in pure H_2O for 5 h	No	Bamboo carbonization (slight); both bamboo and solution turn brown
Soaking in 3 M acids (*e.g.*, HCl, H_2SO_4, *etc.*) at RT for 5 h	No	No changes
Hydrothermal treatment (150°) in 3 M acids (*e.g.*, HCl, H_2SO_4, *etc.*) for 5 h	Yes but rough & poor	Heavy carbonization (both bamboo and solution turn black); huge weight loss; fibers (diameter > 50 μm) are rigid and fragile
Soaking in 3 M alkalis (*e.g.*, NaOH, KOH, *etc.*) at RT for 5 h	No	Slight weight loss (∼3–6%) of bamboo; the soaking solution turns yellow
Hydrothermal treatment (150°) in 3 M alkalis (*e.g.*, NaOH, KOH, *etc.*) for 5 h	Yes	Soft bamboo microfibers (3–6 μm in diameter) are well extracted and uniformly dispersed in solution after a slight ultrasonic process

high-quality bamboo fibers (3–6 μm) are harvested merely in 3 M alkalis, instead of in 3 M acids or neutral water (see optical/ SEM observations in Fig. S6†). Even though rough fibers with a mean diameter of ∼30 μm (marked by arrows in Fig. S6D†) are also yielded after a hydrothermal process conducted in acids, the as-formed products are substantially carbonized and become rather rigid/fragile, being simultaneously accompanied by remarkable morphological changes (*e.g.*, structural collapse in some regions) and huge weight losses up to ∼63%. The resultant carbonization may be induced by complicated inter-molecular dehydration, hydrolysis and condensation/polymer-ization of the organics (like oligosaccharides, hemicelluloses or other molecules in bamboo biomass) in neutral/acid atmo-sphere when the hydrothermal temperature is held at 150 °C.[18]

3.3 Performance of the carbon fibers in LIBs

LIBs performance of derived carbon fibers was evaluated using coin-type half cells, in which Li metal foils are used as the counter and reference electrode. Cyclic voltammetry (CV) is initially used to examine the charge storage behavior of carbon fibers at a scanning rate of 0.5 mV s^{-1} over a potential range of 0.005–3.00 V *vs.* Li/Li$^+$ (Fig. 4A). In the 1st CV scan, there is a cathodic peak present over a wide region attributed to complex phase transi-tions caused by Li intercalation into carbonaceous fibers. An evident reduction peak emerges at 0.435 V but disappears in subsequent cycles, which is related to irreversible electro-chemical processes like trap of Li$^+$ ions in lattices, electrolyte decomposition and formation of solid electrolyte interface (SEI) layer covered on the carbon surface.[19] The redox reactions of Li insertion/extraction in the following cycles becomes highly reversible. Li-intercalation reactions take place below ∼0.5 V (the capacity contribution within ∼0.5–0.85 V is ascribed to faradic capacitive reactions on the carbon fiber surface) while the broad anodic peak related to a Li-deintercalation process launches at ∼0.28 V, consistent with the cases of carbon species derived from biomass in pioneering works.[2c,5a,12c] The CV curves for the 2nd, 3rd and even 50th cycle nearly overlap with each other, suggest-ing a highly reversible and electrochemically stable performance of the carbon-fiber electrode.

Galvanostatic charge–discharge tests have been conducted at ∼0.37 C (1 C = 372 mA g^{-1}) for 800 cycles (Fig. 4B) to estimate the long-term cyclic behavior of carbon fibers. For comparison, unseparated bulky bamboo carbons (see SEM observations in Fig. S7C and D†) with an average size of ∼100 μm are also tested. The electrode of carbon fibers exhibits initial discharge and charge capacities of ∼500 mA h g^{-1} and ∼283 mA h g^{-1}, respectively. By contrast, the bulk bamboo carbons show a bit higher initial discharge capacity (up to ∼535 mA h g^{-1}) but a much lower reversible charge capacity of ∼208 mA h g^{-1}. This implies that carbon fibers possess better reversibility than their bulky counterpart, with an upper initial Coulombic efficiency of ∼56.6%. This value is definitely higher than that of bamboo carbons (∼38.8%), and even comparable to that of transitional metal oxides.[20] For carbon fibers, the evident decrease in the irreversible capacity loss during the 1st cycle may be due to the individual fibrous geometric features; in the kinetics, Li$^+$ may not tend to be trapped because carbon fibers, the active host materials have been perfectly isolated and dispersed for the ease of Li$^+$ intercalation/deintercalation. Both electrodes show a trivial capacity reduction among the prime 30 cycles and later a capacity rise in subsequent steps. The specific capacity of carbon fibers rises from the bottom capacity of ∼256 mA h g^{-1} to ∼355 mA h g^{-1} with a growing rate of ∼0.25 mA h g^{-1} per cycle and then stabilizes at ∼360 mA h g^{-1}, which is more than the practical capacity of commercial graphite (∼300–330 mA h g^{-1}) and the capacity values of other carbon materials.[2c,3c,5a,21a] Note that similar activation results have been reported on carbon-/silicon-based materials.[21] We believe that this capacity-rise phenomenon may result from two aspects as follows. Within prime tens of cycles, the capacity of carbon fibers begins to recover from the minimum value. The origin of this activa-tion is mainly attributed to the delayed infiltration of an elec-trolyte into the carbon fibers.[21c] Around 100 cycles later, the repeated Li insertion/deinsertion process would gradually disrupt carbon fibers preferably at the structural defects. Fibers breaking may lead to more open-up places and accordingly provide more active sites available for Li storage. Besides, Li ions can go through such open-up regions and further diffuse a
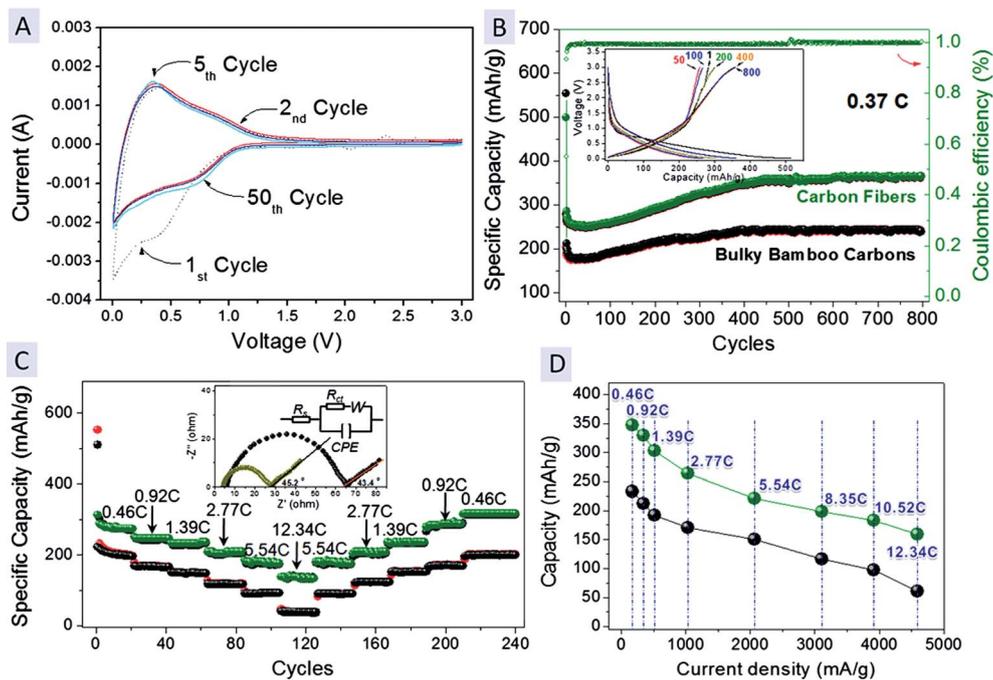

Fig. 4 (A) CV curves of carbon fibers electrode between 0.005 and 3.0 V at a scanning rate of 0.5 mV s^{-1}. few nanometers deep into carbon fibers, which may lead to a continual capacity rise until the entire carbon fiber has been fully utilized. Despite bulky bamboo carbons also having

excellent cycling stability and undergoing a similar capacity-increasing process, the delivered capacity is maintained at a level of ~250 mA h g^{-1} (~110 mA h g^{-1} less than that of carbon

This journal is © The Royal Society of Chemistry 2014

fibers and far below the practical standard), and the ramped rate is only $\sim$0.15 mA h g^{-1} per cycle. Galvanostatic charge–discharge tests at programmed C rates are further carried out to examine their rate capability (Fig. 4C). The electrode of carbon fibers is primarily subjected to continuous cycling under varied current densities, successively at 0.46 C (171 mA g^{-1}), 0.92 C (342 mA g^{-1}), 1.39 C (517 mA g^{-1}), 2.77 C (1030 mA g^{-1}), 5.54 C (2060 mA g^{-1}) and 12.34 C (4590 mA g^{-1}) followed by charge–discharge cycles with currents switching back to 0.46 C. The corresponding records on the relationship between the reversible capacity and the current density have been summarized in Fig. 4D. The capacity of a carbon fiber electrode can fully recover or even surpass its former values upon continuously switching the current rates, capable of delivering a maximum capacity up to 353 mA h g^{-1} (at 0.46 C), 319 mA h g^{-1} (at 0.92 C), 292 mA h g^{-1} (at 1.39 C), 254 mA h g^{-1} (at 2.77 C) and 211 mA h g^{-1} (at 5.54 C), respectively. All these values are higher than those of bamboo carbons. Note that when the current suddenly jumps to 12.34 C (4590 mA g^{-1}; cells charged–discharged in less than 1 min), the electrode of carbon fibers still retains a capacity of $\sim$137 mA h g^{-1}, which is definitely beyond the value of bamboo carbons ($\sim$59 mA h g^{-1}) and other hard carbon materials;[2c] more strikingly, this value is even a bit higher than that of highly conductive carbon nanotubes (CNTs) measured at 10 C (3720 mA g^{-1}).[3c] The above results highlight both the excellent rate capability and capacity retention of derived carbon fibers, showing a great promise to function as an alternative anodic substitute for graphite in LIBs. Electrochemical impedance spectroscopy (EIS) recorded in the frequency range of 1×10^6 to 0.01 Hz under open-circuit conditions is shown in the inset of Fig. 4C. The data fitted from the semicircle in high frequency range reveal the electrode of carbon fibers has a low charge-transfer resistance (R_{ct}) of $\sim$24 Ω (substantially lower than that of bulky bamboo carbons ($\sim$61 Ω)), evidencing the individual carbon fibers possess better electrolyte infiltration and charge-transport capability than the bulk. In the low frequency range, a comparison toward the fitting line slope illustrates carbon fibers electrode exhibits less Warburg impedance (Z_w), which represents a significant parameter associated with the diffusion of Li$^+$ ions along the inter-space of graphitic carbons.[22] The above impedance spectra suggest the electrode of carbon fibers undergoes a fast Faradaic process and has a lower activation energy for Li$^+$ diffusion into graphitic lattices. Even after deep cycling, the R_{ct} of carbon fibers does not change a lot (Fig. S8†). Apart from the electrochemical testing/analysis, we also compare the cost of anodic materials made from chopsticks-derived carbon fibers with the commercially used graphite (see Table S1†). The unit prices given out are all referenced in the recent literature[5a] and the global trade website http://Alibaba.com. Assuming each coin-type cell contains $\sim$100 mg active anode materials, the use of carbon fibers would bring about around $30–41 for manufacturing 10 000 cells in lab. The total amount is lower than that of graphite ($39–54), implying the cost advantage of evolved carbon fibers for LIBs industry.

Though carbon fibers are proven superior to bulky bamboo carbons and competent in sustainability, the battery performance and cost (raw materials are renewable and all recycled from wastes) with graphite (a type of limited fossil/mineral resource), their energy density is yet problematic to meet the ever-growing demand for modern energy-storage applications. Aimed to upgrade their energy density, we have tried various strategies to optimize carbon fibers, either by growth of functionalized metal oxides on each fiber scaffold or doping active elements (like B, N, F and P etc.) on/into the fibrous carbon host.[23-25] One model example is the promotion of the anodic performance by constructing carbon-coated MnO$_2$ nanowires (NWs) on the carbon fibers, forming a smart sandwich-like hybrid (denoted as C/MnO$_2$ NWs/carbon fibers). The choice of MnO$_2$ as an incorporated electrode material is mainly given by factors like manufacturing complexity, environment friendliness, cost and natural abundance. Another notable reason is that unlike other transition metal oxides with conversion reactions occurring above $\sim$1 V,[14a,18c,24] MnO$_2$ has a low lithiation plateau of $\sim$0.5 V vs. Li/Li$^+$ (approaching the value of carbon species). This is definitely below the lowest unoccupied molecular orbital (LUMO) of liquid organic electrolyte but still keeps higher than the Li-reduction potential, enabling generation of stable protective passivation layers on the anode surface to ensure cyclic durability and simultaneously avoiding a yield of detrimental Li dendrites for safety.[4] An XRD measurement has clearly identified the formation of C/MnO$_2$ NWs/carbon fibers hybrid after a series of post-treatments (see Fig. S9A†). Fig. 5A–C show representative SEM images of C/MnO$_2$ NWs/carbon fibers hybrid products. The samples geometrically inherit the fibrous features and possess intriguing hierarchical structures consisting of a carbon fiber inner core and MnO$_2$ NWs outer shells. According to the above XRD record and the HRTEM observation (Fig. S9B†), the produced oxide is identified as α-type MnO$_2$ within a space group of $I4/m$. In addition to being immobilized as a robust shell (shell thickness: 3–5 μm) on each carbon fiber surface, a uniform carbon layer with few-nanometer thickness is intimately coated on MnO$_2$ NWs, as confirmed a by high-resolution TEM observation (Fig. S9C,† see arrows) and Raman spectrum (inset in Fig. 5B; Raman peaks at 505, 572 and 630 cm^{-1} corresponds to distinct Mn–O stretching modes of MnO$_2$ while the ones located at 1342 and 1576 cm^{-1} are fingerprints for the thin carbon layer). As a consequence, nanostructured MnO$_2$ with a high theoretical capacity of $\sim$1230 mA h g^{-1} has been perfectly encapsulated into a carbon matrix (by referring to the thermogravimetric analysis (TGA) in Fig. S10B,† the mass ratio of MnO$_2$ in C/MnO$_2$ NWs/carbon fibers is determined to be $\sim$45.7%). Such designed electrode architecture is quite favorable for LIBs application, alleviating the problems led by self-aggregation and intrinsically low electronic conductivity of MnO$_2$, as well as the lithiation-induced stresses. As a proof-of-concept demonstration of such hybrid products in LIBs, we have evaluated the hybrid of C/MnO$_2$ NWs/carbon fibers (CV and charge–discharge curves are successively present in Fig. S10C and D†). Also, we compare the cyclic behavior of MnO$_2$/carbon fibers (without carbon coating) and pristine carbon fibers. Fig. 5D displays their cyclic performance at 0.2 A g^{-1} in a potential range of 0.005–3 V. C/MnO$_2$ NWs/carbon fibers hybrid electrode delivers initial discharge–charge capacities of 1105 mA h g^{-1} and 706 mA h g^{-1}, respectively. The

capacity loss can be attributed to: (i) irreversible intercalation of Li$^+$ into carbon fibers, (ii) irreversible conversion of MnO_2 with Li$^+$, and (iii) the formation of SEI film on electrode surfaces. The reversibe discharge capacity after 300 cycles is still kept at $\sim$710 mA h g^{-1} (nearly two times that of pristine carbon fibers and far higher than that of MnO_2/carbon fibers electrode), showing 93.8% retention of the 2nd discharge capacity. Fig. 5E shows the programmed cyclic responses of the hybrid products at varied current densities. Along with the increase of current rates from 0.2 to 6 A g^{-1}, the electrode of C/MnO_2 NWs/carbon fibers still exhibits stabilized cyclic behavior, with maximum discharge capacities of 706, 578, 532, 478, 398 and 241 mA h g^{-1} at 0.2, 0.4, 0.8, 1.6, 3.2 and 6.4 A g^{-1}, respectively. Even when the current abruptly jumps back to 0.2 A g^{-1}, the electrode is even able to deliver a higher reversible capacity of $\sim$715 mA h g^{-1}. These results exclusively confirm the enhanced energy-storage and rate capabilities of C/MnO_2 NWs/carbon fibers hybrids over the pristine carbon fibers and the single-phased MnO_2 anode.[26] The high capacity retention and outstanding rate behavior are mainly ascribed to the synergy effects between MnO_2 and the carbon matrix. On one hand, nanostructured MnO_2 with a large surface to volume ratio ensures the delivery of a high specific capacity for the hybrid electrode of C/MnO_2 NWs/carbon fibers. On the other hand, the inner carbon fibers backbone functions as the robust scaffold and electric cables for electrons transfer, whereas the uniform carbon layers on the outer surface of MnO_2 NWs are responsible for positive mechanical protections.

4. Conclusions

In summary, a facile and scalable approach was developed to transform the bamboo chopsticks waste into carbon fibers for LIBs application. The recycled bamboo chopsticks are merely subjected to a simple and controllable delignification process conducted in alkaline aqueous solutions. The natural cellulose fibers in bamboo can then be separated and dispersed automatically. It is confirmed that the reaction time and alkali concentration are both key parameters for controlling the whole fibre extraction process. The obtained natural fibers are further evolved into graphitic carbon fibers after carbonization treatment. When evaluated as anode of LIBs, the derived carbon fibre products show a comparable anodic performance to practical graphitic materials, and far better electrochemical behavior than unseparated bulky bamboo carbons in specific energy and high-rate capabilities. The electrode performance of carbon fibers can be optimized by growing nanostructured metal oxides (typically like MnO_2) robustly on a carbon fiber surface, leading to the formation of an appealing 3D synergetic core–shell electrode architecture. The as-designed hybrid electrode of C/MnO_2 NWs/carbon fibers has been verified as an excellent anode material for LIBs, with good cycling performance ($\sim$710 mA h g^{-1} without decay lasting 300 cycles) and excellent rate performance. The enhanced electrochemical performance is ascribed to the combination of carbon fibers, robust backbone and conducting cable, and C/MnO_2 NWs firmly anchored to the carbon fibers surface, forming a unique core–shell electrode architecture with great synergetic effects.

This work provides a facile and effective way to evolve bamboo chopsticks waste into useful carbon fibers, and more importantly supplies a sustainable and cost-effective platform to develop advanced carbon-based materials for practical use, not merely in LIBs but also in other fields like biosensors, wave absorption, etc.
