Homoleptic low-valent polyazides of group 14 elements†

Benjamin Peerless, Theo Keane, Anthony J. H. M. Meijer and Peter Portius*

First examples of coordinatively unsaturated, homoleptic azido complexes of low-valent group 14 elements are reported. A simple strategy uses low-valent precursors, ionic azide transfer reagents and bulky cations to obtain salt-like compounds containing $E(N_3)_3^-$ of $Ge(\shortparallel)/Sn(\shortparallel)$ which are fully characterised, including XRD. Remarkably, these compounds are kinetically stable at r.t. and isolable in sub-gram quantities.

Binary azides are known for all elements in group 14 and exist as covalent $E(N_3)_4$ compounds (E = C, Si), as hyper-coordinate $E(N_3)_6^{2-}$ complexes (Si-Pb)¹ and as E(N₃)₂ compounds (Sn, Pb). ^{5c} However, no low-valent, homoleptic group 14 complex has yet been reported. All known binary p-block azides are highly endothermic primary explosives most of which possess exceedingly high electrostatic and friction sensitivities and a propensity to release N2. As covalent, N-rich compounds, their isolation is generally challenging and experimental characterisation is limited.⁵ In contrast, stability-inducing effects of hyper-coordination and of bulky, weakly coordinating counter ions (WCC)⁶ allow many salt-like homoleptic polyazides to be synthesised in bulk and characterised fully, including via X-ray crystallography and IR spectroscopy, 5a owing to azide groups (N₃) giving rise to intense bands in the mid-IR region. It has been shown that azide anions (N_3^-) are able to coordinate to low-valent centres in compounds such as $E(L)(N_3)$ and $E(L')(N_3)_2$, E = Ge, $Sn.^{3,4}$ On the other hand, the stability of low valent molecules, e.g. carbenes, silylenes, germylenes, stannylenes, increases by saturating the electron deficient centre with sterically demanding, electron donating groups, such as N-based $C(N^iPr)_2(N^iPr_2)$ and $HC\{(CMe)(2,6^{-i}Pr_2C_6H_3N)\}_2$ ligands. 7a,d This insight has led to tri- and tetracoordinate complexes bearing uni-, bi- and terdentate ligands, e.g. E(NHC)X₂, Ge(NHC)₂Cl⁺ and $Ge\{HB(Me_2pz)_3\}Cl$, E = Si, Ge; X = Cl-I, N_3 ; NHC = N-heterocyclic carbene. 4a,8 Exploitation of these concepts has permitted the

Scheme 1 Synthesis of azido(chloro) germanates (1—) and stannates (1—), E = Ge, n = 1 (1, 3); E = Sn, n = 0 (2, 4); $WCC = AsPh_4$ (a), PPh_4 (b), $N(PPh_3)_2$ (PPN, c).

synthesis and characterisation of the first low-valent and homoleptic Ge and Sn azides described in this paper.

Compounds already containing WCC ions and low-valent germanium, AsPh₄GeCl₃, PPh₄GeCl₃, PPNGeCl₃ (ref. 10) (1a-c), were prepared in high yield from the GeCl2(diox) adduct18 and WCC chlorides19 (Scheme 1, route A).‡11 These colourless, moderately air sensitive crystalline trichlorogermanates react readily with THF suspensions of NaN3. In situ IR spectra of the reaction (2b) show bands due to asymmetric NNN stretches, $\nu_{as}(N_3)$, typical for coordinated N₃ groups at $\bar{\nu}_{\text{max}}/(\text{cm}^{-1})$ = 2092 and 2058, which have grown fully after a reaction time of 1 h. Exposure of the reaction solution to fresh NaN3 results in no further spectral change. From the solution, a highly air sensitive, colourless solid (3b) was precipitated, the IR spectrum of which exhibits the finger print of PPh₄⁺ and the $\nu_{as}(N_3)$ bands. The $\nu_{as}(N_3)$ frequencies lie within the range of those reported previously for semi-covalent germanium(II) azides (2027-2077 cm⁻¹, Fig. 1), below those of Ge(v) azides $(Ge(N_3)_4, PPN_2Ge(N_3)_6, 5c)^{1b}$ and above that of the N₃⁻ ion. While solution ¹H, ¹³C and ³¹P NMR spectra of 3b show signals of the WCC cations only, two peaks are observed in the 14 N NMR spectra at -263 and -207 ppm next to the solvent (-136 ppm) with FWHM line widths of 552, 147 and 24 Hz, respectively. These characteristics are typical for the N_{α} and N_{γ} nuclei of coordinated N_3 groups while the signal for N_{β} is obscured by solvent.5a

Alternative routes to 3 and 4 use WCC azides as azide transfer reagents. GeCl₂(diox) reacts directly also with (PPN)N₃

in MeCN solution (Scheme 1, route B). Intriguingly, equimolar reactant mixtures produce only one $\nu_{as}(N_3)$ band (2078 cm $^{-1}$); increasing the stoichiometric ratio (1:2) results in two additional bands (2088, 2066 cm $^{-1}$), while at ratios of 1:9 and above only bands at 2095, 2064 cm $^{-1}$ and that of N_3^- were detected. These observations are interpreted tentatively in terms of the formation of mono, di- and triazido complexes.

Tin dichloride was subjected to a similar treatment as $GeCl_2(diox)$ using $WCC(N_3)$ and NaN_3 ; however, complete Cl/N_3 exchange requires a larger excess of azide transfer reagent. Similar observations as with 3b were made, including the intermediate rise and decay of a $\nu_{as}(N_3)$ band (2064 cm⁻¹) and the ultimate rise of bands of the final product 4b (2081, 2050 cm⁻¹) in the expected region between $Sn(N_3)_6^{2-}$ and charge-neutral Sn(II) monoazides (Table S1, ESI†), and ¹⁴N resonances at -218.5 ppm (FWHM ≈ 32 Hz) and -260.0 ppm (166 Hz). The ¹⁴N NMR signals of 3b and 4b, in particular those assigned to N_{cs} , are deshielded in comparison to those of $E(N_3)_6^{2-}$ dianions. ^{1b,5a,17} 3b and 4b are soluble in MeCN, THF and CH_2Cl_2 .

The synthetic strategy was extended to $AsPh_4^+$ and PPN^+ counter ions affording compounds 3a,c and 4c (Scheme 1A) which all have spectroscopic properties analogous to those of 3b and 4b described already. The combined analytical evidence, including the absence of chlorine in 3b and the ^{119}Sn NMR signal of 4b ($\delta = -220$ ppm, see ESI†) point to the formation of anionic complexes in compounds of the type (WCC)E(N₃)₃ as the final products of Cl/N₃ exchange.

Further insight into the nature of intermediates and products of the exchange reactions was obtained from quantum chemical calculations²⁰ on the $ECl_{(3-n)}(N_3)_n^-$ species, which were performed at the B3LYP/cc-pVTZ level²¹ with effective core potentials²² for Ge and Sn. Solvent (THF) was described using PCM.²³ The calculations found conformational isomerism resulting in several minima for n = 1, 2, 3, that were close in energy. These conformers are related by rotation of ligands. Since rotational barriers of sterically unhindered N_3 groups are

small (cf. GeH₃N₃, ~ 1 kJ mol⁻¹), ¹³ fast interconversion involves all significantly thermally populated rotamers above the minimum energy conformation ($E_{\rm rel}$ < 5.8 kJ mol⁻¹). This process is likely to result in averaged absorption bands weighted by the rotamer population (rotamers may have more than one degenerate, absolute spatial configuration, and inter-rotamer vibrational energy transfer is unaccounted for). Taking account of the theoretical equilibrium mole fractions, absorption intensities and scaled vibrational frequencies,24 approximate average frequencies of the in-phase and out-of-phase $\nu_{as}(N_3)$ stretches and the qualitative intensity ratios could be determined (Table S1, ESI†), which match those observed (e.g. $Ge(N_3)_3^-$, 2059, 2091 vs. 2060, 2093; $Sn(N_3)_3^-$, 2051, 2080 vs. 2050, 2078 cm $^{-1}$). This approach leads to the assignment of the observed bands of intermediates to $GeCl_2(N_3)^-$, $GeCl(N_3)_2^-$, $SnCl_2(N_3)^-$ and $SnCl(N_3)_2^-$. Calculations using the Gauge-Independent Atomic Orbital method²⁵ verify the assignment of 14N NMR data (see ESI†).

Crystals of azido germanates were grown from THF–Et $_2$ O (1:10) solutions at $-18~^{\circ}$ C (3b, needles) or by diffusion of Et $_2$ O into concentrated THF solutions (3c).§¶ According to single crystal X-ray diffraction studies, 3b consists of PPh $_4^+$ and Ge(N $_3$) $_3^-$ ions (Fig. 2). The shortest interionic Ge···N and N···N distances were found to be 4.13 and 5.07 Å, respectively (Fig. 4, left), hence, covalent {[Ge(N $_3$) $_3^-$]-···{[Ge(N $_3$) $_3^-$] interactions are absent (Fig. 3). Germanium is coordinated by three, essentially linear N $_3$ ligands and occupies the apical position in a trigonal-pyramidal Ge[N] $_3$ framework. The ligands are bound in the fashion typical of covalent azides and adopt Ge–N $_\alpha$ –N $_\beta$ angles between 116° and 121°. All inter-ligand angles are close to 90° which indicates stereochemical inactivity of the lone electron pair at germanium. 14

This structural feature has been found in the valence isoelectronic complexes of $Ge_2(\mu\text{-pz}^*)_3^+$ $GeCl_3^-$ (ref. 11f) and pilocarpine-trichlorogermanate hemihydrate. The $Ge-N_\alpha$ bonds of $3\mathbf{b}$ are shorter than those of tetracoordinate $Ge(\pi)$ azides 2.088(6)–2.094(7) Å (Fig. 1), longer than those of the homoleptic $Ge(\pi)$ azide $PPN_2Ge(N_3)_6$ ($\mathbf{5c}$, Table S1, ESI†) and rather within the range of previously investigated, tricoordinate $Ge(\pi)$ azides

(1.969–2.047(2) Å, Table 1). All other bond lengths and angles are close to those of **5c** (Table 1). The crystallographic structure of $Ge(N_3)_3$ is consistent with one of the geometries predicted by DFT (*vide supra*).

Single crystalline needles of 4b were obtained and investigated with the methods used for $3b.\P$ The asymmetric unit of

4b also contains a $E(N_3)_3$ moiety; however, the packing is at variance with 3b, which allows $Sn(N_3)_3$ to interact *via* two long $E \cdot N_{\alpha}$ bonds and form $\{Sn(N_3)_3\}_2^{2-}$ dimers (Fig. 3). The interaction involves asymmetric $\mu_{1,1}$ -N₃ bridges with short (2.207(3) Å) and long (2.674(3) Å) Sn-N_{\alpha} bonds, the latter being considerably shorter than the sum of the van der Waals radii (3.72 Å).16 Weak intermolecular interactions have been observed previously between neutral Sn(ⁿPr₂ATI)N₃ complexes (vide supra), 4b where a slightly longer Sn···N_{α} bond (2.87 Å) was found. The sum of bond angles involving the bridging N_{α} indicates planarity and effective sp² hybridisation. As in the crystal of 3b, the primary $E(II)-N_{\alpha}$ bonds are significantly longer (2.193(3)-2.262(3) Å) than those found in the homoleptic E(IV) azide 6 (2.125 Å). The potential for dimerisation was studied by DFT using the geometry of $\{E(N_3)_2(\mu_{1,1}-N_3)\}_2^{2-}$ in crystalline 4b as a starting point. Optimisation results in separate anions devoid of covalent interionic interactions in the case of $Ge(N_3)_3$, whereas a dimeric structure was found for $Sn(N_3)_3$ that resembles the molecular structure in the crystal. Estimates of the basis set superposition error for the solution phase were obtained from BSSE calculations²⁶ in the gas phase. After BSSE correction, $\{Sn(N_3)_2(\mu_{1,1}-N_3)\}_2^{2-}$ was found to be at least 4 kcal mol⁻¹ less stable than two monomers, rendering the existence of a dimer in solution highly unlikely.

According to differential scanning calorimetry measurements (Fig. S11 and S12, ESI†), compound 3b decomposes in two exothermic processes with ($\Delta H = -270$ and -467 J g⁻¹). Remarkably, step 1 occurs at temperatures ($T_{\rm on}^{\rm ex1}$ = 99 °C) that are drastically below the decomposition onset of the related, hypercoordinate azide 5c ($T_{\text{on}}^{\text{ex1}} = 256 \,^{\circ}\text{C}$), ^{1b} whereas step 2 sets in at $T_{\rm p}^{\rm ex2}$ = 310 °C, which is nearly identical with the temperature found in 5c (312 °C).** Furthermore, the molar enthalpies of step 2 $(-251 \text{ vs. } -482 \text{ kJ mol}^{-1})$ scale approximately with the complex charge; however, step 1 releases much less energy than expected (145 kJ mol^{-1} , 3b vs. 705 kJ mol^{-1} , 5c). This phenomenon is still under investigation. Further experiments show that heating of 3b at 150 °C produces PPh₄N₃, which suggests that the release of N_3^- initiates the decomposition of $Ge(N_3)_3^-$. The tin homologue 4b melts at $T_{\rm on}$ = 115 °C and decays at 215 °C and 308 °C and thus behaves as expected relative to **6c.** 15 No sensitivity was noted during preparation and analysis of compounds 3b and 4b on the stated reaction scale. The material remains unchanged when struck by a hammer. Upon lighting up, it burns rapidly with an orange flame leaving black residues.

In solution, $Ge(N_3)_3^-$ and $Sn(N_3)_3^-$ react with hydrazoic acid leading to a precipitate with the IR $\nu_{as}(N_3)$ absorptions characteristic for $Ge(N_3)_6^{\ 2-}$ and $Sn(N_3)_6^{\ 2-}$ complexes, respectively,

which can be verified by comparison with spectra of the fully characterized salts 5c, 6c (Scheme 2, Fig. S13 and S14, ESI†).

The first low-valent homoleptic azido complexes of group 14 have been synthesized and fully characterised. The preparative approach to salt-like compounds containing these complexes has been demonstrated on a 0.2-0.7 g scale for a range of weakly coordinating cations and involves chloro(azido) species, $ECl_x(N_3)_v^-$. Unlike their hypercoordinate $E(N_3)_6^{2-}$ analogues and despite the presence of innocent cations, the new class of compounds is highly reactive, exhibiting low thermal stability and a propensity to oxidation. Crystallographic analysis revealed that in the solid state, E(N₃)₃ complexes of group 14 may dimerise via azido ligand bridges. Neither of the low-valent coordination centres exhibits a stereochemically active lone electron pair. DFT calculations correctly predict the dimerisation and suggest furthermore that the dimers are unstable in polar solvents.

The authors thank the EPSRC (EP/E054978/1), the University of Sheffield and Humboldt-Universität zu Berlin for support and Prof. A. C. Filippou for advice.
