Red-to-blue triplet–triplet annihilation upconversion was obtained in giant unilamellar vesicles. The upconverted light was homogeneously distributed across the membrane and could be utilized for the imaging of individual giant vesicles in three dimensions. These results show the great potential of TTA-UC for imaging applications under anoxic conditions.

Upconversion luminescence (bio)imaging offers great advantages over conventional imaging. The absence of auto-fluorescence results in high contrast images, while photons of low energy, i.e. within the phototherapeutic window (600–1000 nm), afford higher tissue penetration and negligible irradiation damage. For these reasons lanthanoid-based upconverting nanoparticles (UCNPs), for example, have attracted much interest. However, UCNPs suffer from several disadvantages, such as the need for high excitation power, the low absorption cross section of lanthanoid ions, and low upconversion efficiency in aqueous solution (typically ≤ 0.5%). In contrast, triplet–triplet annihilation upconversion (TTA-UC) requires low excitation power (< 100 mW cm⁻²), employs sensitizers having high extinction coefficients in the singlet state, whereas the other one falls back to the ground state. Higher tissue penetration and negligible irradiation damage. Further collision of two triplet annihilator molecules leads to triplet–triplet annihilation (TTA), whereby one annihilator molecule is promoted to the excited singlet state, whereas the other one falls back to the ground state. The singlet annihilator returns to the ground state by emission of a high-energy photon, thus realizing upconversion. Most molecular dyes used in TTA-UC are highly lipophilic and require supramolecular strategies to be used in aqueous solution. For example, sub-micrometer sized TTA-UC particles have been proposed for in vitro or in vivo imaging. We now demonstrate that TTA-UC can also be used for the imaging of lipid membranes.

Giant Unilamellar Vesicles (GUVs) are classical tools in fluorescence imaging, as their large size (1–100 μm) allows for direct observation of individual vesicles by optical microscopy techniques. GUVs have for example been used for visualizing lipid rafts, membrane fusion, or ion transport. In this study we functionalized PEGylated GUVs with palladium tetraphenyltetrabenzoporphyridin (1) as photosensitizer and perylene (2) as the annihilator (Fig. 1a), and studied red-to-blue TTA-UC in the membrane of the vesicles by optical microscopy. The aim of the study was to investigate the dye distributions across the membrane, the homogeneity of upconverted emission in the lipid bilayer, and the upconversion stability under imaging conditions. The growth of high-quality giant vesicles with a well-defined shape in physiologically relevant conditions, i.e., at high ionic strengths, was until recently considered as a challenge, but a new method was recently developed by some of us that is compatible with such conditions (up to 320 mOsm kg⁻¹).

Upconverting giant vesicles GUV12 were thus prepared from a lipid mixture of 95 mol% phospholipid (either 1,2-dimyristoyl-sn-glycero-3-phosphocholine, i.e. DMPC, or 1,2-dioleoyl-sn-glycero-3-phosphocholine, i.e. DOPC), 4 mol% sodium N-(carboxymethoxypolyethylene glycol-2000)-1,2-distearoyl-sn-glycero-3-phosphoethanolamine (DSPE-MPEG-2000), 0.5 mol% compound 2, and 0.02 mol% compound 1. The complete procedure is described in the ESI. Briefly, the dye-containing lipid mixture in chloroform was deposited on a chemically cross-linked dextran–poly(ethylene glycol) hydrogel substrate, dried to form

a lipid film, and then the film was re-hydrated with phosphate buffered saline (PBS) supplemented with 0.3 M sodium sulfite (Na₂SO₃) and 0.2 M sucrose at 293–308 K. Transferring the solution onto a microscopy slide allowed for bright field imaging on a custom-build microscope based on an inverted microscopy setup. The images (Fig. 1c) confirmed that for both lipid compositions (DMPC or DOPC) free-floating single vesicles were obtained, together with clusters of smaller vesicles. The images also show that the self-assembled vesicles were giant (diameter 1–100 μm), unilamellar, and spherical. The fact that almost identical procedures can be employed for preparing GUVs from lipids having a marked difference in their gel-to-liquid transition temperature (T_m = −17.3 °C and 23.9 °C for pure DOPC and DMPC, respectively), 18 demonstrates the flexibility of the GUV preparation method. For comparison, much smaller LUVs (samples LUV12) with an average diameter of ca. 150 nm were prepared from the same lipid mixture but using a standard hydration-extrusion protocol (ESI† Fig. S2).

Sodium sulfite was added in the buffer as an oxygen-scavenging agent. Since the triplet states involved in TTA-UC are readily quenched by molecular oxygen, it is common practice to deoxygenate samples before measuring upconverted emission. With LUVs de-oxygenation can be achieved by, for example, bubbling the solution with argon or N₂. In the case of GUVs imaging, however, bubbling an inert gas through the solution would at least impair visualization of single GUVs during a long time period of time due to convection, or even lead to damaging of the giant vesicles, so that supplementing the buffer with an oxygen scavenger is highly preferred. In a preliminary experiment, upconversion emission spectra of LUV12 samples deoxygenated by either argon bubbling for 30 minutes or by adding 0.3 M sodium sulfite to the buffer, were compared (see Fig. S4 and ESI† for details). When irradiated at 630 nm the emission spectrum of such LUVs at 298 K shows at 800 nm the phosphorescence band of 1, and between 450 and 600 nm the blue singlet emission from 2 (Fig. S4, ESI†). The spectra from both deoxygenation methods were found to be very similar. It was thus concluded that Na₂SO₃ does not interfere with the photo-physical processes at the origin of upconversion, and that sulfite might be used for scavenging dioxygen in a GUV-containing sample as well.

Indeed, even though addition of Na₂SO₃ significantly increased the ionic strength of the buffer (from 278 ± 1 mOsm kg⁻¹ for PBS buffer to 884 ± 11 mOsm kg⁻¹ when supplemented with 0.3 M sodium sulfite), as explained above sodium sulfite did not prevent the assembly of DMPC or DOPC GUV12 using the hydrogel method. No differences in vesicle yield and morphology were observed in presence or absence of sodium sulfite in the buffer. This result demonstrates that the dextran–poly(ethylene glycol) hydrogel substrate is able to produce GUVs at high ionic strength, which is a significant advantage over alternative GUV preparation methods such as electroformation or gentle hydration, which often fail in such conditions. When irradiated at 630 nm under air, the emission spectrum of the DMPC or DOPC GUV12 samples prepared in a sulfite-supplemented buffer was identical to the emission spectrum of the corresponding LUV12 samples (Fig. 1b and Fig. S4, ESI†), showing that the dyes 1 and 2 were indeed incorporated in the lipid bilayer.

GUV12 samples were then visualized by emission microscopy at 298 K (Fig. 2 and ESI†). When the vesicles were illuminated with violet light (405 nm), i.e. by direct excitation of perylene (2), fluorescence was clearly detected at the membrane (Fig. 2b). To visualize upconversion, a 630 nm continuous wave PDT laser was coupled into the microscope and set at a power of a few milliwatts, resulting in the focal spot in an intensity of ~300 W cm⁻². All wavelengths other than 450–575 nm were strictly blocked by a combination of notch and short-pass filters (ESI†). High-quality images were obtained that were superimposable to the bright field images and to the fluorescence images recorded under white and violet light irradiation, respectively (Fig. 2a–c). Control samples were prepared in which the porphyrin sensitizer 1 was omitted from the formulation [GUV2]. Images recorded in identical conditions were black, i.e., no blue emission was observed (Fig. S10, ESI†). GUV12 samples prepared in absence of sulfite oxygen scavenger and observed under air did not give any observable emission either (Fig. S11, ESI†). Altogether, these observations prove that the blue images recorded under 630 nm irradiation of GUV12 samples supplemented with sulfite comes from the TTA upconversion process and are not the result of sensitizer emission (at 800 nm) or of two-photon absorption. Overall, all data conclude that both dyes 1 and 2 co-localize in the membrane and result in TTA upconversion. At this scale of observation the upconverted emission is homogeneous across the membrane and no phase separation of the lipids or dyes was observed.

Under the red-light irradiation conditions initially used in the microscopy setup (630 nm at an intensity of 320 W cm⁻²), substantial bleaching of the upconverted emission of GUV12
samples was observed even in presence of 0.3 M of sulfite. A plot of the averaged normalized pixel values as a function of red irradiation time shows that the upconverted emission is halved after less than 3 seconds (Fig. 3). When the light intensity was lowered 60 times (i.e., down to 5.2 W cm$^{-2}$) clear upconversion images could still be recorded. In such conditions, the bleach rate was significantly lower (Fig. 3), and the time necessary for halving the upconverted emission intensity of a pixel increased to approximately 15 seconds. The upconversion luminescence of LUV12 in a spectroscopy setup could be observed for less than 8 mW cm$^{-2}$, with linear power dependency above 60 mW cm$^{-2}$ (Fig. S6, ESI†). Overall, these findings show that high power is not a requirement for the upconversion imaging of GUV12.

In optimized conditions, we realized that the upconverted emission was intense enough to be utilized for reconstructing in 3D the membrane of the giant vesicles. Z-stack upconversion image acquisition was indeed performed on both DMPC and DOPC GUV12 samples. The illumination intensity was deliberately chosen to be high (320 W cm$^{-2}$) to make sure that z-stack image acquisition was short (200 ms exposure time per slice, ca. 45 slices per stack, total acquisition time < 10 s). In such conditions, the slight lateral motion of the GUVs did not significantly affect the imaging process. From these stacks, 3D reconstructions were made (e.g. Fig. 4), of which a video was compiled (Video V1 in the ESI†). This reconstruction demonstrates that the TTA-upconverted emission can be utilized for the three-dimensional reconstruction of an object that is 10 to 30 μm in size.

In conclusion, DOPC and DMPC giant vesicles capable of upconverting red light to blue light by means of triplet–triplet

![Fig. 2 Imaging of DOPC (left) and DMPC (right) upconverting giant vesicles (GUV12) with (a) bright field, (b) 405 nm excitation and 450–500 nm detection, and (c) 630 nm excitation and 450–575 nm detection. (d) Upconversion intensity profile plot following the arrows in the images directly above (c). At 630 nm: laser spot size diameter 39 μm, power 3.8 mW, intensity 320 W cm$^{-2}$. At 405 nm: laser spot size diameter 22 μm (power 1 mW), intensity 60 W cm$^{-2}$) for DOPC image or 39 μm (power 1 mW, intensity 300 W cm$^{-2}$) for DMPC image. Images were acquired at 298 K in sulfite-supplemented (0.3 M) PBS buffer.

annihilation were prepared by lipid film hydration on a hydrogel substrate at high ionic strengths. The preparation method is facile and does not involve any specific equipment. Sodium sulfite added as an oxygen scavenger to the vesicle samples allows for observing upconversion even under air. According to optical microscopy, the upconverted emission allows for recording high quality images showing that upconversion is homogeneously realized across the lipid bilayer. The quality and stability of the upconverted images enabled the 3D reconstruction of upconverting GUVs. These results show the great potential of TTA upconversion for imaging applications under anoxic conditions, and open a route towards cell membrane imaging with upconverted light.

Notes and references

Fig. 4 3D reconstructed image of a DMPC GUV12 sample, rotated counter-clockwise by 50° about the y-axis. Each z-slice was imaged at 298 K with 630 nm excitation (320 W cm⁻²) and detection in the 450–575 nm region. The z-distance between slices was 1.0 µm. Video V1 (ESI†) exhibits a 360° rotational view of this image and of four other individual DMPC and DOPC GUV12.
