A kinetic study of the CH\textsubscript{2}OO Criegee intermediate self-reaction, reaction with SO\textsubscript{2} and unimolecular reaction using cavity ring-down spectroscopy†

Rabi Chhantyal-Pun, a Anthony Davey, a Dudley E. Shallcross, a Carl J. Percival b and Andrew J. Orr-Ewing a

Criegee intermediates are important species formed during the ozonolysis of alkenes. Reaction of stabilized Criegee intermediates with various species like SO\textsubscript{2} and NO\textsubscript{2} may contribute significantly to tropospheric chemistry. In the laboratory, self-reaction can be an important loss pathway for Criegee intermediates and thus needs to be characterized to obtain accurate bimolecular reaction rate coefficients. Cavity ring-down spectroscopy was used to perform kinetic measurements for various reactions of CH\textsubscript{2}OO at 293 K and under low pressure (7 to 30 Torr) conditions. For the reaction CH\textsubscript{2}OO + CH\textsubscript{2}OO (8), a rate coefficient \( k_8 = (7.35 \pm 0.63) \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{s}^{-1} \) was derived from the measured CH\textsubscript{2}OO decay rates, using an absorption cross section value reported previously. A rate coefficient of \( k_4 = (3.80 \pm 0.04) \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{s}^{-1} \) was obtained for the CH\textsubscript{2}OO + SO\textsubscript{2} (4) reaction. An upper limit for the unimolecular CH\textsubscript{2}OO loss rate coefficient of 11.6 \pm 8.0 s\textsuperscript{-1} was deduced from studies of reaction (4). SO\textsubscript{2} catalysed CH\textsubscript{2}OO isomerization or intersystem crossing is proposed to occur with a rate coefficient of \( (3.53 \pm 0.32) \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{s}^{-1} \).

Introduction

In 1949 Rudolph Criegee \(^1\) proposed that an intermediate (later to be called a Criegee intermediate) was formed during the ozonolysis of alkenes. On addition of ozone to an alkene a primary ozonide (POZ) is formed which decomposes to form a carbonyl and a Criegee intermediate (CI).\(^2\textsuperscript{-4}\) Taking ethene as an example, the following reaction sequence leads to the formation of the simplest CI, CH\textsubscript{2}OO.

\[
\text{H}_2\text{C} = \text{CH}_2 + \text{O}_3 \rightarrow \text{CH}_2\text{CHOO} \rightarrow \text{CH}_2\text{CO} + \text{H}_2\text{O}
\]

The Criegee intermediate formed can undergo rapid unimolecular decomposition, often to yield OH radicals,\(^5\textsuperscript{-7}\) but a second much slower decomposition has been observed and attributed to so called stabilised CI (SCI).\(^6\textsuperscript{-7}\) These SCI are formed with internal energies below the threshold to unimolecular decomposition and are sufficiently long lived to undergo reaction with atmospheric trace gases. SCIs were postulated but remained undetected in the gas-phase until the work of Taatjes and co-workers,\(^8\textsuperscript{-12}\) who showed that these SCIs could be generated through photolysis of allyl diiodide species in the presence of oxygen, e.g.

\[
\text{CH}_2\text{I}_2 + h\nu \rightarrow \text{CH}_2\text{I} + \text{I}
\]

\[
\text{CH}_2\text{I} + \text{O}_2 \rightarrow \text{CH}_2\text{OO} + \text{I}
\]

\[
\text{CH}_2\text{I} + \text{O}_2 + \text{M} \rightarrow \text{ICH}_2\text{O}_2 + \text{M}
\]

This breakthrough has led to many recent studies that have investigated the UV/visible,\(^13\textsuperscript{-19}\) IR\(^20,21\) and microwave\(^22\textsuperscript{-24}\) spectra, as well as several kinetic studies of CH\textsubscript{2}OO and CH\textsubscript{3}CHOO with SO\textsubscript{2}, NO, NO\textsubscript{2}, carbonyls, alkenes and organic acids.\(^8\textsuperscript{-11,16,25\textsuperscript{-30}}\) Direct studies, i.e. ones that monitor the decay of SCI or a proxy of the SCI (e.g. HCHO, OH) return rate coefficients that are considerably larger than previous indirect estimates based on end product analysis.\(^2\) These new kinetic data suggest a greater role for SCI species in the atmospheric oxidation of SO\textsubscript{2} and NO\textsubscript{2} in particular.

Field measurements support a role for the SCI assisted production of H\textsubscript{2}SO\textsubscript{4} (ref. 31) and although model studies disagree as to the extent, they do agree that there is a non-negligible impact of CIs on oxidation of SO\textsubscript{2}.\(^32\textsuperscript{-34}\) If the gas-phase...
oxidation of SO$_2$ to SO$_3$ (and subsequently H$_2$SO$_4$) by SCI competes with, or even dominates in regions of the lower troposphere, over the oxidation by OH, the formation of H$_2$SO$_4$ may be accelerated and aerosol nucleation rates affected.$^{32,33}$

\[
\text{CH}_2\text{OO} + \text{SO}_2 \rightarrow \text{HCHO} + \text{SO}_3 \quad (4)
\]

\[
\text{OH} + \text{SO}_2 \rightarrow \text{HOSO}_2 \quad (5)
\]

There is considerable debate concerning the impact of these new data, with models predicting effects ranging from significant through to more modest. Given the differences in chemical scheme used in these various model studies as well as model resolution, current disagreement on SCI impact remains to be resolved. However, models that contain detailed chemistries, e.g. the Master Chemical Mechanism$^{35}$ and its surrogate the Common Representative Intermediates scheme,$^{33}$ return a more significant impact than those models with less hydrocarbon chemistry.$^{34}$ A major issue at the core of these discrepancies concern the two loss processes that dominate the SCI concentration, unimolecular loss and reaction with water vapour:

\[
\text{CH}_2\text{OO} \rightarrow \text{Products} \quad (6)
\]

\[
\text{CH}_2\text{OO} + \text{H}_2\text{O} \rightarrow \text{Products} \quad (7)
\]

Welz et al., Li et al., and Percival et al. noted that significant SCI levels are predicted if $k_6$ is around 200 s$^{-1}$ or less and if $k_7$ is less than around $1 \times 10^{-16}$ cm$^3$ molecule$^{-1}$ s$^{-1}$. Further work is required to determine $k_6$ and $k_7$ more accurately.

Recent work has shown that the rate coefficient for the self-reaction of CH$_2$OO (reaction [8]) is very large.$^{35}$

\[
\text{CH}_2\text{OO} + \text{CH}_2\text{OO} \rightarrow 2\text{HCHO} + \text{O}_2 \quad (8)
\]

Although this reaction has no atmospheric relevance, it could be important in laboratory studies that probe the kinetics and mechanisms of alkene ozonolysis.$^{36}$ In this paper we report measurements of $k_6$, $k_7$, and $k_8$ at room temperature over a range of pressure, using near UV cavity ring-down spectroscopy (CRDS) to detect CH$_2$OO. Where appropriate, we compare with previously reported rate coefficients obtained using alternative methods.

**Experimental**

Cavity ring down spectroscopy was used to probe temporal profiles of CH$_2$OO signals in flowing gas samples using the known $\tilde{B}^1\Pi_A \leftarrow \tilde{X}^1\Pi_A$ electronic absorption band in the near ultraviolet (UV) spectral region. UV probe radiation was generated by frequency doubling the visible radiation output of a dye laser (Sirah CobraStretch, with pyridine 1 dye) pumped by the second harmonic of a Nd:YAG laser (Continuum Surelith III-10). A probe wavelength of 355 nm was chosen to maximize CH$_2$OO absorption$^{13,16}$ and minimize interferences. The ESI$^+$ provides detailed discussion of possible interferences and their elimination.

The third harmonic of a Continuum Surelith I-10 Nd:YAG laser ($\lambda = 355$ nm; 100 mJ per pulse; energy density $\sim 500$ mJ cm$^{-2}$, <10 ns pulse duration) was used to photolyze CH$_2$I$_2$ to start the chemistry leading to production of CH$_2$OO. The unfocused photolysis beam had a diameter of 5 mm with a top-hat intensity profile, and crossed the probe beam (with beam waist of 0.24 mm) at an angle of 5°, giving an overlap length of 5.7 cm in the centre of the CRDS cavity. The delay between the two laser pulses was controlled by a BNC 555 digital delay generator.

High reflectivity mirrors ($R > 99.9\%$ at 355 nm, 100 cm radius of curvature) were mounted 106 cm apart at opposite ends of a glass tube to form the ring-down cavity. Light escaping from one end mirror of the cavity was monitored by a photodiode (New Focus 1801) and digitized by an 8 bit oscilloscope (LeCroy Waverunner 6030; 350 MHz, 2.5 GSamples per s). Typical ring-down times $< 6 \mu$s were much shorter than the 1–10 ms timescales used for reaction kinetics measurements under our experimental conditions.

The 6 cm diameter glass tube confined the flow of reagent and bath gases along the detection axis of the spectrometer. The flow rates for all gases were regulated by calibrated mass flow controllers (MKS 1479A and 1179A). The precursor molecule, diiodomethane (CH$_2$I$_2$, 99%), and sulphur dioxide (SO$_2$, $\geq 99.9\%$) were purchased from Sigma-Aldrich. CH$_2$I$_2$ was purified further by freeze–pump–thaw cycling before use. High purity nitrogen ($N_2$) and oxygen ($O_2$) were obtained from Air Liquide. Pre-mixtures of CH$_2$I$_2$ in $N_2$ (0.7 Torr/750 Torr) and SO$_2$ in $N_2$ (5 or 750 Torr/1500 Torr) were made and allowed to mix for at least a day to obtain a homogenous mixture. Low flows (20 sccm) of nitrogen were passed through purge lines close to the ring down mirrors to prevent mirror contamination. All the other gases were passed into the flow tube through a port close to the centre of the cavity. 1.0 to 2.0 Torr of the precursor premixes, 1.0 Torr of oxygen and various pressures of nitrogen were used for the experiments. Sample pressures were measured by two capacitance manometers (0–10 Torr and 0–1000 Torr) located close to the centre of the flow tube. Total flow rates (excluding the mirror purges) ranged from 50–500 sccm, and we verified that the purge flows did not significantly change the overall column length of the gas mixture used in kinetic studies over the total pressure range 7–30 Torr by measuring absorption by CH$_2$I$_2$ or added NO$_2$. We obtained average gas sample lengths of 37 ± 3 cm that are a factor of 6.5 longer than the overlap region of the photolysis and probe laser beams in which the chemistry of interest occurs. The arrangement of the overlap of the probe and much-larger diameter photolysis laser beams gives a flat concentration profile across the probe region at early times, and diffusion out of the probe volume is expected to be a first order process. We also calculate that mass flow across the probe volume will have negligible effects over the timescales of our kinetic measurements.

Further details of the spectrometer and optimization of experimental conditions are provided in the ESI$^+$.†

**Results and discussion**

**(1) CH$_2$OO + CH$_2$OO reaction**

Relatively high concentrations of CH$_2$OO need to be produced in laboratory experiments in order to provide enough signal for kinetic measurements. In the present work, typical initial CH$_2$OO concentrations of $2.5\times10^{12}$ molecule cm$^{-3}$ were generated. Under such conditions, the self-reaction can contribute
significantly to the overall loss of CH$_2$OO. Recently, Su et al. reported a CH$_2$OO self-reaction rate constant of $k_a = (4 \pm 2) \times 10^{-10}$ cm$^3$ molecule$^{-1}$ s$^{-1}$ by monitoring depletion of infrared bands.$^{35}$ This value was refined to $k_a = (6.0 \pm 2.1) \times 10^{-11}$ cm$^3$ molecule$^{-1}$ s$^{-1}$ by Buras et al., by simultaneous monitoring of the near UV band of CH$_2$OO and near IR absorption of iodine atoms.$^{37}$ Recently, Ting et al. reported a $k_a$ value of $(8 \pm 4) \times 10^{-11}$ cm$^3$ molecule$^{-1}$ s$^{-1}$ using broadband UV absorption spectroscopy and monitoring CH$_2$OO depletion along with that of CH$_3$I and IO.$^{38}$ Reaction of CH$_3$I with O$_2$ was used to produce CH$_2$OO in all of these studies. Using photoionization mass spectrometry, this chemical route was shown to produce sufficient CH$_2$OO radical concentration to perform kinetic measurements.$^9$ In this work we used a similar reaction pathway shown by reactions (1) and (2) to produce CH$_2$OO. Other than the self-reaction, we also considered the following removal pathways for CH$_2$OO and I.

$$\text{CH}_2\text{OO} + \text{I} \rightarrow \text{ICH}_2\text{O}_2 + \text{M} \quad (9)$$

$$\text{CH}_2\text{OO} + \text{I} \rightarrow \text{ICH}_2 + \text{O}_2 \quad (10)$$

$$\text{CH}_2\text{OO} + \text{I} \rightarrow \text{HCHO} + \text{IO} \quad (11)$$

$$\text{CH}_2\text{OO} + \text{ICH}_2\text{O}_2 \rightarrow \text{Products} \quad (12)$$

$$\text{I} + \text{I} + \text{M} \rightarrow \text{Products} \quad (13)$$

Under our experimental conditions, CH$_3$I is expected to react with O$_2$ within the first time step (200 $\mu$s) of the kinetic measurements. The branching ratio of reactions (2) and (3) determines the yield of CH$_2$OO which increases with a decrease in the concentration of the third body (M). Under low pressure conditions and in the absence of other reactant species, the self-reaction (8), and reactions (9)-(11) with iodine atoms, are expected to be the major loss mechanism for CH$_2$OO. At higher pressures, contribution from reaction (12) will increase. Assuming the fast self-reaction to be the dominant loss mechanism, the decay traces of CH$_2$OO were fitted to an integrated second order decay expression. Further justification for this fitting procedure is provided later. For a second order decay mechanism,

$$\frac{dN}{dt} = -2k_{obs}N^2 \quad (14)$$

in which $k_{obs}$ is the effective second order decay rate coefficient, $t$ is time and $N$ is the CH$_2$OO concentration. The integrated second order decay rate expression is

$$N(t) = \frac{N(t_0)}{1 + 2k_{obs}N(t_0)t} \quad (15)$$

In eqn (15), $N(t_0)$ is the initial CH$_2$OO concentration. In our cavity ring-down measurements, probe light intensity decay rate constants, $\kappa$, (or ring-down times, $\tau = 1/\kappa$) are measured with and without the photolysis laser on to give a transient absorption signal. The concentration of the absorbing species is given by

$$N(t) = \frac{\Delta\kappa(t)L}{c_0d\sigma_{355\text{nm}}} \quad (16)$$

where $\tau_{on}$ and $\tau_{off}$ are ring-down times with the photolysis laser on and off, $L$ is the length of the cavity, $c$ is the speed of light, $d = 5.7$ cm is the photolysis and probe laser overlap length, $\sigma_{355\text{nm}}$ is the absorption cross-section of CH$_2$OO at the probe wavelength 355 nm and the change in ring-down rate, $\Delta\kappa$, is directly proportional to the CH$_2$OO concentration. Characterization of the overlap length is presented in the ESI.$^\dagger$ Combining eqn (15) and (16) gives

$$\Delta\kappa(t) = \frac{1}{\Delta\kappa(t_0)} + \left(\frac{2}{c_0d}\right)k'l$$

$$k' = \frac{k_{obs}}{\sigma_{355\text{nm}}} \quad (19)$$

where $k'$ is the observed second order decay rate coefficient scaled with respect to the CH$_2$OO absorption cross section at 355 nm. Uncertainty in the absorption cross section of CH$_2$OO at the probe wavelength determines the uncertainty in the $k_{obs}$ value, and as such a cross-section independent value is desired. Thus, the effective second order decay coefficient is expressed in terms of $k'$, which can be readily converted to a second-order rate coefficient for a given choice of value for $\sigma_{355\text{nm}}$.

The ESI$^\dagger$ summarizes possible sources of interferences at the 355 nm probe wavelength and our procedure for their elimination. The interference-subtracted decay traces were fitted to eqn (18) as exemplified by the data shown in Fig. 1. Data points starting from a 200 $\mu$s time delay to around 10 ms were included in the fit. Reaction (2) is calculated to have a half-life of 11.8 $\mu$s based on the bimolecular rate coefficient of $1.82 \times 10^{-12}$ cm$^3$ molecule$^{-1}$ s$^{-1}$ (ref. 16) and hence is expected to be complete by 200 $\mu$s. Experimental conditions were selected such that the CH$_2$OO signal depletes by greater than 90% by a photolysis-probe delay of 10 ms. Under such conditions, non-second order loss mechanisms like diffusion and mass flow do not contribute significantly to the decay mechanism, as discussed in the Experimental section. Details of the experiments to characterize the non-second order loss mechanisms in the detection region of the flow tube are presented in the ESI.$^\dagger$

CH$_2$OO decay traces were obtained for different initial concentrations of the CH$_2$OO (see ESI$^\dagger$) and at different bath gas (N$_2$) pressures. Fig. 2 shows the fitted $k'$ values obtained from kinetic decay traces as a function of the bath gas concentration. These values are also provided in Table S4 in the ESI.$^\dagger$ The quality of the second order fits for the CH$_2$OO decay traces under all the pressure conditions (7 to 30 Torr) is excellent, with adjusted $k'$ values greater than 0.99. A second order decay form of the type used in the analysis is strictly valid for a bimolecular reaction in which the two reactants are of equal concentrations. Thus, the extracted $k'$ values should derive primarily from the self-reaction of CH$_2$OO or reaction of CH$_3$OO with similar concentrations of other molecules like ICH$_2$OO, I atom or a mixture of both. The obtained values show a positive
dependence on N₂ bath gas pressure. The I atom yield is expected to decrease with increasing pressure, whereas the contribution from the reaction between ICH₂OO and CH₂OO should increase with an increase in pressure. The CH₂OO self-reaction rate coefficient has been calculated to be independent of pressure,30,35. The pressure range studied in the current work offers a window in which the third body concentration, which lowers the yield of CH₂OO, whereas the rate coefficients for (10) and (11) are calculated to be independent of pressure,35 and could contribute significantly to the CH₂OO loss along with the dominant self-reaction under low pressure conditions. A quantitative analysis of the pressure dependence evident in Fig. 2 is presented in the ESI, and our observations can be accounted for if the rate coefficient for reaction of CH₂OO with ICH₂OO is k₈ ≈ 2 × 10⁻¹⁰ cm³ molecule⁻¹ s⁻¹. This value is consistent with the rate coefficient for CH₂OO + HO₂ of k = 2.23 × 10⁻¹⁰ cm³ molecule⁻¹ s⁻¹ calculated by Long et al.39 and is a factor of ~4 lower than the limiting capture rate for a barrierless reaction that we predict from estimated dipole moments for CH₂OO and ICH₂OO.

The zero pressure limit value for k’ can therefore be taken as an upper limit for the CH₂OO self-reaction rate coefficient k₉ scaled by σ₃₅₅nm (eqn (19)). Table 1 shows the k₁obs values obtained by using the zero pressure limit k’ value and the σ₃₅₅nm values reported by various sources. The CH₂OO σ₃₅₅nm value from the work of Ting et al. is expected to be the most accurate as the CH₂OO σ₃₅₅nm value reported in their study is similar to the value obtained by Buras et al. using a different method. Thus, with incorporation of the quoted uncertainty for σ₃₅₅nm values, k₈ ≤ 7.98 × 10⁻¹¹ cm³ molecule⁻¹ s⁻¹ is the best estimate for the self-reaction rate coefficient of CH₂OO from this empirical approach.

To estimate the contributions from reactions (10) and (11) to the value of k₁obs, numerical kinetic fits were performed for the 7 Torr total pressure CH₂OO decay trace. This chosen decay trace should have minimum contribution from the pressure dependent reactions. The I atom self-reaction, (13), CH₂OO + I reaction and the CH₂OO self-reaction, (8), were used in the model for the numerical fit. The CH₂OO + I reaction takes into account the combined effects from reactions (10) and (11) and kiodine is taken as its overall rate coefficient. The initial I atom concentration was fixed to twice the CH₂OO concentration and a rate coefficient value of 2.83 × 10⁻¹⁵ cm³ molecule⁻¹ s⁻¹ was used for reaction (13), obtained using a kinetic rate coefficient expression (M = N₂ = 7 Torr, T = 298 K) reported previously.40 Fig. 3 shows the results of the fits obtained by varying the kiodine values while floating the k₈ values. No significant contribution from kiodine was found as the fits obtained with the kiodine value floated and with no contribution from the CH₂OO + I reaction (i.e. kiodine = 0 cm³ molecule⁻¹ s⁻¹) were identical. The kiodine value could not be determined from these fits because the dominant removal process for CH₂OO is self-reaction (k₈ > kiodine) under our conditions. The fits obtained by using kiodine values of 0.5 and 1.0 × 10⁻¹¹ cm³ molecule⁻¹ s⁻¹ are of significantly lower quality, consistent with the observations of Buras et al. The k₈ values obtained from these different fits are listed in Table 2.

Table 1. Effective second order decay rate coefficient, k’ = k₁obs/σ₃₅₅nm, for the loss of CH₂OO at the low pressure limit. The values of k₁obs reported in the fourth column are obtained using σ₃₅₅nm values from various sources.

a The value of σ₃₅₅nm (with uncertainty on the order of a factor of 2) was obtained from a Gaussian fit to the spectrum reported by Beames et al.
reaction to the overall CH$_2$OO decay is expected to be either similar, or perhaps larger, in the pressure range used in the current work. However, the CH$_2$OO decay profiles obtained in the current study are predominantly second order. Contrary to the observations of Buras et al., we see a definite increase in the effective second order rate coefficient value with pressure, most likely because of contributions from reactions (9) and (12) (see above, and ESI†). These contributions, instead of the CH$_2$OO + I reaction, might cause the decay of CH$_2$OO to assume first-order behaviour with further increase in pressure, and could explain the observations of purely second order CH$_2$OO decay in the current work and the combined first and second order decays of Buras et al. Nevertheless, both approaches should be equivalent in principle to separate the contributions from the self-reaction and other reactions of CH$_2$OO.

Inclusion of the CH$_2$OO self-reaction could be important in the kinetic models for analysis of the end-products of alkene ozonolysis reactions used to determine the consequences of Criegee intermediate chemistry in the atmosphere. However, the scope of the current work is to obtain bimolecular reaction rate coefficients for the reaction of CH$_2$OO with atmospherically relevant species and inclusion of the overall second order loss of CH$_2$OO in kinetic analysis schemes should suffice. Further detailed discussion of the contribution of the second order loss of CH$_2$OO in the presence of other reagents is presented in the ESI.† Inclusion of the second order loss mechanism will be especially important to characterize accurately the small, but atmospherically relevant, rate coefficients for reactions of CI with species like H$_2$O. Also, in the CH$_2$H$_2$ + O$_2$ synthesis method, the CH$_2$OO second order loss contribution increases with pressure as shown in Fig. 2, and thus should be included in the analysis of experimental results obtained at higher pressures.

(II) CH$_2$OO + SO$_2$ reaction

CH$_2$OO oxidizes SO$_2$ to SO$_3$ (reaction (4)) and hence may contribute to atmospheric sulphuric acid production. The bimolecular reaction rate of CH$_2$OO + SO$_2$ has been characterized extensively under low pressure and ambient temperature conditions via direct and indirect studies. These reaction rate coefficients have been used to verify the presence of CH$_2$OO and to obtain its near-UV absorption spectrum. However, direct studies at atmospherically relevant pressures and temperatures are still lacking. This section presents some preliminary work on the effect of extending the pressure range and the inclusion of the self-reaction in the analysis to obtain the reaction rate coefficient of CH$_2$OO with SO$_2$ using the

Taking $1.0 \times 10^{-11}$ cm$^3$ molecule$^{-1}$ s$^{-1}$ as a conservative upper limit estimate for $k_{\text{iodine}}$, the fitted $k_a$ value (6.83 ± 0.13) $\times 10^{-11}$ cm$^3$ molecule$^{-1}$ s$^{-1}$ is taken as a lower limit. Combining this lower limit estimate with the upper limit estimate from the empirical analysis and propagating the uncertainties, a value of (7.35 ± 0.63) $\times 10^{-11}$ cm$^3$ molecule$^{-1}$ s$^{-1}$ is obtained as the best estimate for $k_a$ in the current work.

The $k_a$ value obtained from the current work is compared with ones reported previously in Table 3. Our $k_a$ value is well within the bounds of uncertainty of the value reported by Buras et al.$^{27}$ Both of these values are significantly lower than the one reported by Su et al.$^{35}$ Although the $k_a$ values from this work and the work of Buras et al. agree well, the analyses performed are quite different. Their kinetic study was performed by monitoring absorbance of CH$_2$OO and I atoms. A kinetic model was used to obtain the upper limit for the CH$_2$OO + I rate coefficient that simultaneously fitted I atom and CH$_2$OO decay traces, taking into account self-reactions, unimolecular losses, and cross-reactions. However, a simpler model showed that the CH$_2$OO + I reaction is in the pseudo first order limit, and the work of Buras et al. shows that the CH$_2$OO self-reaction and this pseudo first order reaction of CH$_2$OO and I. Both of these approaches led Buras et al. to suggest a maximum rate coefficient value of $1 \times 10^{-11}$ cm$^3$ molecule$^{-1}$ s$^{-1}$ for the overall reaction of I atom with CH$_2$OO, so the self-reaction dominates. The yields for both I atom and CH$_2$OO increase with a decrease in pressure, and thus the pseudo first order contribution of the CH$_2$OO + I reaction to the overall CH$_2$OO decay is expected to be either similar, or perhaps larger, in the pressure range used in the current work. However, the CH$_2$OO decay profiles obtained in the current study are predominantly second order. Contrary to the observations of Buras et al., we see a definite increase in the effective second order rate coefficient value with pressure, most likely because of contributions from reactions (9) and (12) (see above, and ESI†). These contributions, instead of the CH$_2$OO + I reaction, might cause the decay of CH$_2$OO to assume first-order behaviour with further increase in pressure, and could explain the observations of purely second order CH$_2$OO decay in the current work and the combined first and second order decays of Buras et al. Nevertheless, both approaches should be equivalent in principle to separate the contributions from the self-reaction and other reactions of CH$_2$OO.

Inclusion of the CH$_2$OO self-reaction could be important in the kinetic models for analysis of the end-products of alkene ozonolysis reactions used to determine the consequences of Criegee intermediate chemistry in the atmosphere. However, the scope of the current work is to obtain bimolecular reaction rate coefficients for the reaction of CH$_2$OO with atmospherically relevant species and inclusion of the overall second order loss of CH$_2$OO in kinetic analysis schemes should suffice. Further detailed discussion of the contribution of the second order loss of CH$_2$OO in the presence of other reagents is presented in the ESI.† Inclusion of the second order loss mechanism will be especially important to characterize accurately the small, but atmospherically relevant, rate coefficients for reactions of CI with species like H$_2$O. Also, in the CH$_2$H$_2$ + O$_2$ synthesis method, the CH$_2$OO second order loss contribution increases with pressure as shown in Fig. 2, and thus should be included in the analysis of experimental results obtained at higher pressures.
direct methods. It also explores a possible catalytic isomerization or intersystem crossing (ISC) of CH$_2$OO in the presence of low concentrations of SO$_2$ that is proposed to account for some of our experimental observations.

CH$_2$OO decay traces obtained in the presence of SO$_2$ are expected to have contributions from both first and second order loss mechanisms

$$\frac{dN}{dt} = -2k_{\text{obs}}N^2 - k_{\text{pseudo}}N$$

(20)

here, $k_{\text{pseudo}}$ is the pseudo first order rate constant for reaction of CH$_2$OO with SO$_2$ which is present in excess. This rate coefficient can, in principle, also contain contributions from mass flow and diffusion, though these are considered small on the $\leq$1 ms timescale of the measurements reported below (see ESI†). The second order contribution is provided by bimolecular reactions of CH$_2$OO, reactions (8), (10) and (11), the overall rate coefficient for which was obtained in the previous section. Eqn (20) is a simple form of Bernoulli’s differential equation, the analytical solution for which is provided in ref. 41.

$$N(t) = \frac{k_{\text{pseudo}}N(t_0)}{k_{\text{pseudo}}e^{k_{\text{pseudo}}t} - 2k_{\text{obs}}N(t_0) + 2k_{\text{obs}}N(t_0)e^{k_{\text{pseudo}}t}}$$

(21)

combining eqn (16) and (21) gives

$$\Delta k(t) = \frac{k_{\text{pseudo}}}{k(t) - k_{\text{pseudo}}e^{k_{\text{pseudo}}t} - k'(\frac{1}{C_0}) + k'\frac{1}{C_1}e^{k_{\text{pseudo}}t}}$$

(22)

The $k'$ values were fixed to the values obtained from the previous section, whereas $\Delta k(t_0)$ and $k_{\text{pseudo}}$ values were floated in the fits. This analysis requires no assumption to be made about the correct value of $\sigma_{355\text{nm}}$. Fig. 4 shows the decays of CH$_2$OO signal in the presence of different concentrations of SO$_2$. The SO$_2$ concentration range used and the robustness of the pseudo first order approximation are justified in detail in the ESI†. These decay traces were fitted to eqn (22) to obtain $k_{\text{pseudo}}$ values for each SO$_2$ concentration. Fig. 5 shows the $k_{\text{pseudo}}$ values as a function of SO$_2$ concentration. The gradient of a linear fit gives the CH$_2$OO + SO$_2$ bimolecular reaction rate coefficient.

CH$_2$OO decay traces in the presence of SO$_2$ were measured for different total pressures in the flow tube. The N$_2$ pressure was varied while keeping the O$_2$ (1 Torr) and CH$_3$I$_2$–N$_2$ premix (1 Torr) pressures constant to alter the total pressure. Experiments were conducted for several [SO$_2$] values to allow pseudo first-order analysis under all total-pressure conditions. Fig. 6 shows the CH$_2$OO + SO$_2$ bimolecular reaction rate coefficients, $k_4$, as a function of total pressure obtained from this work and from previous studies. These values are also provided in Table S4 in the ESI†. The $k_4$ values obtained at different pressures agree within the error of the fits and a pressure independent $k_4$ value, $(3.80 \pm 0.04) \times 10^{-11}$ cm$^3$ molecule$^{-1}$ s$^{-1}$, is obtained by taking an error weighted average. This value is in excellent agreement with the previously reported values$^{9,16}$ also obtained via direct measurement of CH$_2$OO.

The $k_4$ values obtained previously at higher pressures via methods monitoring HCHO$^{28}$ or OH$^{26}$ fluorescence show no dependence on pressure, in agreement with the results obtained

![Fig. 4 CH$_2$OO decay traces in the presence of various concentrations of SO$_2$. The initial CH$_2$OO concentration was $\sim 3.3 \times 10^{12}$ molecule cm$^{-3}$. All the decay traces were taken at 10 Torr total pressure. Each individual trace was background subtracted using the method described in the ESI†. The solid lines show the fits performed using eqn (22).](image)

![Fig. 6 CH$_2$OO + SO$_2$ bimolecular reaction rate coefficient as a function of pressure from various sources including the current work. Error bars are 1σ values. The inset key identifies the species monitored in other studies of reaction (4).](image)
in this work for pressures from 10–30 Torr. However, the pressure independent \( k_4 \) values obtained in this work and from other CH\(_2\)OO loss studies are larger than the ones obtained from the more indirect measurements of HCHO or OH production. In the case of the OH fluorescence experiment, OH radicals can form via unimolecular dissociation of CH\(_2\)OO, and the \( k_4 \) value \((3.53 \pm 0.29) \times 10^{-11} \text{ cm}^3 \text{ molecule}^{-1} \text{ s}^{-1}\) was obtained from the linear fit of relatively small pseudo first order rate coefficient values \((150 \text{ to } 250 \text{ s}^{-1})\). Under such conditions, contributions from the second order reaction of CH\(_2\)OO are significant, and correction for this competing pathway for CH\(_2\)OO removal should increase the derived \( k_4 \) value.

(III) CH\(_2\)OO unimolecular reaction

The unimolecular reaction (6) may be an important loss mechanism for CH\(_2\)OO under atmospheric conditions, along with bimolecular reactions with H\(_2\)O.\(^{33}\) No rigorous direct experimental study has been performed so far to obtain a CH\(_2\)OO unimolecular decay rate coefficient. Fig. 4 and 5 illustrate the pseudo first order analysis performed to obtain bimolecular rate coefficient for the CH\(_2\)OO + SO\(_2\) reaction. The intercept value of the linear fit in Fig. 5 should be related to the first order loss of CH\(_2\)OO. Unimolecular decay, diffusion and mass flow across the detection axis of the spectrometer could all contribute to the observed first order loss of CH\(_2\)OO, but we present evidence in ESI† that the latter two effects are small on the \(<1 \text{ ms} \) measurement times of these experiments. There should not be significant contribution from wall loss as the radicals are synthesized and probed at the same region in the middle of the 6 cm diameter flow tube. Second order fits of the CH\(_2\)OO decay traces in the absence of SO\(_2\) do not show significant first order contributions, as exemplified in Fig. 1, because of a small first order contribution relative to the dominant second order CH\(_2\)OO loss process. However, non-zero intercept values \((>500 \text{ s}^{-1})\) were obtained in the pseudo first order analysis at different total pressures, which appear inconsistent with the fits to second order (self-reaction) decays. To resolve this issue, experiments were performed to obtain CH\(_2\)OO decay traces in the presence of lower concentrations of SO\(_2\), more comparable with the CH\(_2\)OO concentration.

Fig. 7 shows the CH\(_2\)OO decay trace obtained at the lowest SO\(_2\) concentration used in the current work, and the fit using eqn (22) to obtain the first order contribution. Although the pseudo first-order approximation might be expected to break down at the lower end of our SO\(_2\) concentration range, numerical modelling shows that a pseudo first-order treatment remains valid because of the rapidity of the CH\(_2\)OO self-reaction. The overall kinetics are still well-described by simultaneous second and first order fits \(\text{[adjusted } R^2 > 0.99\text{]}\). The inset in Fig. 7 shows the non-linear behaviour of the plot of the reciprocal of \(\Delta x\) as a function of time caused by a first order contribution to the dominant second order decay (CH\(_2\)OO self-reaction). Fig. 8 shows the pseudo first order rate coefficients obtained from analysis of the CH\(_2\)OO decay traces taken over our whole range of low to high SO\(_2\) concentrations. We see the onset of curvature in the plot for [SO\(_2\)] values that are still in more than four-fold excess over the initial concentration of CH\(_2\)OO. Separate linear fits were performed for the four highest \((8.64 \times 10^{13} \text{ to } 2.16 \times 10^{14} \text{ molecule cm}^{-3})\) and four lowest \((1.08 \times 10^{12} \text{ to } 6.48 \times 10^{12} \text{ molecule cm}^{-3})\) SO\(_2\) concentrations. The linear fit expressions obtained are \([3.93 \pm 0.13] \times 10^{-11} \times [\text{SO}_2] + 629 \pm 147\) and \([7.46 \pm 0.29] \times 10^{-11} \times [\text{SO}_2] + 11.6 \pm 8.0\) for the high and low SO\(_2\) concentration regimes, respectively. Linear Fit 1 gives the CH\(_2\)OO + SO\(_2\) reaction contribution, whereas linear Fit 2 suggests a different mechanism also contributes at low SO\(_2\) concentrations.

We hypothesize an SO\(_2\)-catalysed but reversible isomerization or ISC mechanism, in competition with reaction to HCHO + SO\(_3\), to explain what we see. A generalized kinetic analysis incorporating the idea is presented in the ESI† and accounts for the observed dependence of \(k_{\text{pseudo}}\) on [SO\(_2\)]. Previous theoretical work by Vereeken et al.\(^{17}\) suggests 17% of the CH\(_2\)OO + SO\(_2\) reaction leads to singlet bisoy radical + SO\(_3\) via a pathway with a submerged energy barrier,\(^{10}\) and this isomerization mechanism is one candidate for our experimental observations. However, we note that the
reversibility of our proposed mechanism conflicts with the calculations of Vereecken et al. which place the ground states of isomers of CH$_2$OO more than 60 kJ mol$^{-1}$ lower in energy than the Criegee intermediate. An alternative candidate is formation of a triplet state species via intersystem crossing and the calculations of Vereecken et al. lend some support to this suggestion. These authors identified that, in the vicinity of the OCH$_2$OS(O)O biradical adduct of CH$_2$OO and SO$_2$, the singlet and triplet states are split by less than 0.4 kJ mol$^{-1}$; at near degeneracy here or elsewhere in the CH$_2$OO – SO$_2$ configuration space, singlet–triplet mixing may be significant and lead to reversible ISC.

In the absence of an alternative explanation for our experimental observations, we are forced to propose an as-yet unidentified intermediate species such as a triplet biradical, or question the accuracy of the existing calculations, which use single reference methods to describe biradical intermediates that (as the authors themselves argue) would be better treated with multi-reference techniques. Our suggested mechanism remains tentative and clearly is subject to testing if multi-reference electronic structure calculations are performed, or the triplet state reaction pathways are mapped. We therefore do not place undue emphasis on this mechanism here, and further details of our model and analysis instead appear in the ESL†.

The analysis based on our proposed mechanism shows that the pseudo first order rate coefficient at high SO$_2$ concentration can be attributed to bimolecular reaction of CH$_2$OO and SO$_2$ but the intercept of fit 1 depends on both the rate coefficient for unimolecular dissociation of CH$_2$OO in the absence of SO$_2$ and that for the intermediate isomer, as well as the ratio of forward and backward isomerization rate coefficients. This analysis is supported by numerical fitting, which is also discussed in the ESL†. The intercept value for Fit 1 does not have significant dependence on total pressure (intercept values at pressures, 10 to 30 Torr, are provided in Table S4 in the ESL†) and a pressure independent value of 704 ± 47 s$^{-1}$ was obtained. In the low SO$_2$ pressure regime, our model indicates that the pseudo first order rate coefficient should be the sum of contributions from bimolecular reaction and catalysed isomerization/ISC by SO$_2$, justification for which is provided in the ESL†. A value of (3.53 ± 0.32) $\times$ 10$^{-11}$ cm$^3$ molecule$^{-1}$ s$^{-1}$ was obtained for the catalysed isomerization/ISC rate coefficient by subtraction and propagation of errors of the slope values obtained from Fit 1 and Fit 2.

The intercept of the low SO$_2$ concentration fit (Fit 2), 11.6 ± 8.0 s$^{-1}$, is taken as an upper limit for the unimolecular loss of CH$_2$OO in the absence of SO$_2$-induced isomerization/ISC, because it may also contain diffusion and mass flow contributions. Unimolecular rate coefficient values from 100 to 200 s$^{-1}$ have been used previously for atmospheric chemistry modelling of stabilized CH$_2$OO. These values were taken as an estimated upper limit from laboratory based studies of CH$_2$OO. Several recent studies have also reported upper limit estimates for the unimolecular loss rate coefficient around 200 s$^{-1}$.[16,26,37] Significant contribution from wall reactions prevented accurate determination of the CH$_2$OO unimolecular loss rate coefficient. Olzmann et al. estimated the CH$_2$OO unimolecular loss rate to be 0.33 s$^{-1}$ based on electronic structure calculations, which is much lower than the estimates from previous kinetic studies using direct sources of CH$_2$OO.[42] The CH$_2$OO unimolecular rate coefficient upper limit value obtained in the current study is more in keeping with the theoretical study. The present study therefore shows that a pathway for CH$_2$OO losses by catalysed isomerization or ISC could bridge the discrepancies between the prior experimental and theoretical estimates.

(IV) Atmospheric implications

SO$_2$ concentrations of 10$^{10}$ to 10$^{11}$ molecule cm$^{-3}$ have been reported in rural and urban environments, respectively.[30] Thus, the CH$_2$OO + SO$_2$ reaction should be in the low pressure limit (for SO$_2$ collisions) in these environments and both the proposed isomerization (or ISC) and bimolecular reaction should be important CH$_2$OO loss pathways. Both of these reactions should also compete with the unimolecular decomposition of CH$_2$OO. Maximum pseudo first order reaction rate coefficients of 12, 1.3 and 1.4 s$^{-1}$ are calculated for the CH$_2$OO unimolecular reaction, the hypothesized SO$_2$-catalysed CH$_2$OO isomerization reaction and CH$_2$OO + SO$_2$ bimolecular reaction using the rate coefficient obtained in this work and a typical atmospheric SO$_2$ concentration of 3.8 $\times$ 10$^{10}$ molecule cm$^{-3}$.[30] The lower limiting value for the unimolecular reaction rate coefficient of CH$_2$OO compared with the one used in a previous modelling study[33] should yield a prediction of higher concentration of stabilized CH$_2$OO in the atmosphere.

The CH$_2$OO + H$_2$O and CH$_2$OO + (H$_2$O)$_2$ reactions are expected to be the most important atmospheric CH$_2$OO loss mechanisms. Pseudo first order reaction rate coefficients for the CH$_2$OO + H$_2$O and CH$_2$OO + (H$_2$O)$_2$ reactions could be as high as 36 and 81 s$^{-1}$ based on maximum rate coefficient estimates of 9 $\times$ 10$^{-17}$ and 3 $\times$ 10$^{-13}$ cm$^3$ molecule$^{-1}$ s$^{-1}$ and typical atmospheric concentration of 4 $\times$ 10$^{17}$ and 2.7 $\times$ 10$^{14}$ molecule cm$^{-3}$ for H$_2$O and (H$_2$O)$_2$ respectively.[12,28,30] Precise measurements of the CH$_2$OO + H$_2$O and CH$_2$OO + (H$_2$O)$_2$ reaction rate coefficients are needed for more accurate estimates. The work of Leather et al. derived a ratio for $k_3/k_6 = 3.3$ $\times$ 10$^{17}$ molecule cm$^{-3}$, and using the upper limit value for $k_6$ obtained in this work leads to an estimate for $k_7 = 3.5$ $\times$ 10$^{17}$ cm$^3$ molecule$^{-1}$ s$^{-1}$ (with a range of 1–6 $\times$ 10$^{17}$ cm$^3$ molecule$^{-1}$ s$^{-1}$ based on the uncertainty in $k_6$ obtained here).[43] These estimates for $k_7$ are smaller but consistent with the work of Stone et al.[26] and larger than the values used in various studies to estimate urban, regional and global CI levels.[3,9,11,12,33] Hence, CI levels in these studies may be underestimated, but caution is needed as the rate coefficient for reaction of CI species with water dimers has come under some scrutiny recently and may be sufficiently large to offset this change. Nevertheless, the possibility of significant levels of CI in the boundary layer in particular are supported by this work.

Conclusions

Rate coefficient values for CH$_2$OO self-reaction, reaction with SO$_2$ and unimolecular reaction were obtained at 293 K and
under low pressure (7 to 30 Torr) conditions using cavity ring-down spectroscopy. Rate coefficient values for the CH2OO self-reaction and reaction with SO2 obtained in the current study are in agreement with previously reported values obtained by different methods. The rate coefficient value for CH2OO unimolecular reaction was found to be significantly lower compared to the estimates from previous experimental studies, but in line with a theoretical estimate. Reversible isomerization or intersystem crossing of CH2OO that is catalysed by SO2 is in line with a theoretical estimate. Reversible isomerization or intersystem crossing of CH2OO that is catalysed by SO2 is proposed to explain the discrepancy between previous experimental estimates and the theoretical calculations.
