Gas phase selective hydrogenation over oxide supported Ni–Au

Fernando Cárdenas-Lizana and Mark A. Keane*

The chemoselective continuous gas phase ($T = 573 K$, $P = 1$ atm) hydrogenation of nitroarenes (p-chloronitrobenzene (p-CN) and m-dinitrobenzene (m-DNB)) has been investigated over a series of oxide (Al$_2$O$_3$ and TiO$_2$) supported Au and Ni–Au (1:10 mol ratio; 0.1–1 mol% Au) catalysts. Monometallic supported Au with mean particle size 3–9 nm promoted exclusive formation of p-chloroaniline (p-CAN) and m-nitroaniline (m-NAN). Selective hydrogenation rate was higher over smaller Au particles and can be attributed to increased surface hydrogen (from TPD measurements) at higher metal dispersion. (S)TEM analysis has confirmed an equivalent metal particle size for the supported bimetallics at the same Au loading where TPR indicates Ni–Au interaction and EDX surface mapping established Ni in close proximity to Au on isolated nanoparticles with a composition (Au/Ni) close to the bulk value (= 10). Increased spillover hydrogen due to the incorporation of Ni in the bimetallics resulted in elevated –NO$_2$ group reduction rate. Full selectivity to p-CAN was maintained over all the bimetallic catalysts. Conversion of m-DNB over the lower loaded Ni–Au/Al$_2$O$_3$ generated m-NAN as sole product. An increase in Ni content (0.01 → 0.1 mol%) or a switch from Al$_2$O$_3$ to TiO$_2$ as support resulted in full –NO$_2$ reduction (to m-phenylenediamine). Our results demonstrate the viability of Ni-promotion of Au in the continuous production of functionalised anilines.

1. Introduction

The combination of two metallic elements has been shown to be an effective means of improving catalytic performance in a range of hydrogen mediated reactions, notably chemoselective hydrogenation (of nitro-compounds$^3$), partial hydrogenation (of alkenes$^2$) and hydrogenolysis (of chlorophenols$^3$). Renewed interest in Au as a catalytic agent has encompassed Au in bimetallic formulations, as noted in the recent review by Villa et al.$^4$ Gold has shown unique selectivity in the hydrogenation of polyfunctional reactants but delivers low reaction rates.$^5$ This drawback has been ascribed to a restricted capacity for $H_2$ activation by dissociative chemisorption.$^6$ The combination of Au with transition metals that exhibit greater $H_2$ chemisorption capability offers a possible means of enhancing hydrogenation rate.

The hydrogenation response over bimetallic catalysts is determined by the structure and physico-chemical properties of the supported nanoparticles, which are dependent on the distribution of both metals within the crystal nanostructure. In order to achieve any degree of catalytic synergy, the two metals must be in close proximity (if not in direct contact) on the support. The size, metal ratio and nature of the support are critical variables. Bimetallic particles at the nano-scale ($\sim 3$ nm) can form solid solutions (homogeneous alloy particles) regardless of the miscibility gap between the two metallic elements.$^7$ The incorporation of a second metal with Au (X–Au, where X = Pd,$^8$ Pt$^9$) has been shown to increase hydrogenation activity but at low Au/X ratios the selectivity response is affected or even governed by the second metal.$^8$ The redox character and acid–base properties of the (oxide) carrier can act to stabilize small Au nanoparticles as a result of electron transfer across the metal–support interface and induce geometric and electronic modifications that impact on catalysis.$^3$

Prior research has focused on binary metals that form (ordered or random) bulk alloys with no miscibility gap in the corresponding bulk phase diagram. This is the case with Pd–Au as the most widely studied Au-containing bimetallic.$^{10}$ Interest has shifted to systems such as Ni–Au that do not mix in the bulk but can form stable alloys in the outermost surface layers.$^{11,12}$ The incorporation of Au onto partially oxidised Ni resulted in partial oxidation of Au atoms and the formation of Au$_x$–O–Ni$_y$ ensembles (from XPS),$^{13}$ which were suggested as active sites in the isomerisation of methylstyrenes over Ni–Al$_2$O$_3$.$^{14}$ Nishikawa et al.$^{15}$ studying the promotional effect of Au on Ni, demonstrated (by XRD, TEM, XAFS and $^{197}$Au Mössbauer) the formation of an Ni–Au alloy, following reduction (to 673 K in $H_2$) of Au/NiO co-precipitates. These were active in the hydrogenolysis of benzylc alcohols with superior catalytic activity compared with RANEY$^{16}$ Ni.

Chin et al. demonstrated by EXAFS/XANES analysis of Ni–Au/MgAl2O4 [prepared by reductive deposition of Au on Ni/MgAl2O4] Au → Ni electron transfer with surface alloy formation that served to inhibit carbon deposition during n-butane steam reforming. The addition of Au to Ni (1 : 4) resulted in the formation of nano-crystals with a Au-core and Ni-enriched shell structure (based on EXAFS, XPS and UV-vis) with increased hydrogenolysis activity in the conversion of 2-phenoxo-1-phenylethanol.17 That work was directed at the continuous selective production of industrially important functionalised amines under mild reactions conditions. Supported Ni-Au delivered higher hydrogenation activities than supported Au. We have refocused our attention and have considered the possible role of Ni (introduced as the minor component; Ni/Au mol/mol = 0.1) to enhance the chemoselective hydrogenation action of Au to deliver enhanced rates to the target amine product. We assessed the feasibility of controlling hydrogenation rate by varying Au particle size and the nature of the oxide support.

2. Experimental

2.1 Catalyst preparation and activation

The Al2O3 (Puralox, Condea Vista Co.) and TiO2 (Degussa) supports were used as received. (HL, 0.1 mol%) and low loaded (LL, 0.01 mol%) Ni/Al2O3 and/or Ni/TiO2 catalyst precursors were synthesised by standard impregnation, where the support (6 g) was contacted with an aqueous Ni(NO3)2 solution (Aldrich, 7 × 10−5–7 × 10−4 M, 85 cm3). The slurry was heated at 2 K min−1 to 353 K and maintained under constant agitation (600 rpm) in a He purge. The solid was dried in a flow of He at 383 K for 5 h and sieved (ATM fine test sieves) to mean particle diameter = 75 µm. The Au–Ni catalyst precursors were prepared by first reducing a batch of (LL and HL) Ni/Al2O3 and (LL) Ni/TiO2 in a (60 cm3 min−1) H2 stream at 2 K min−1 to 723 K, which was maintained for 1 h to ensure formation of zero valent Ni. The gas flow was switched to He, cooled to ambient temperature and the samples passivated in 1% v/v O2/He. This treatment served to provide a protective oxide layer over the surface Ni that prevented bulk oxidation upon exposure to the atmosphere. The passivated samples were treated with an aqueous HAvCl4 solution (Aldrich, 3 × 10−5–5 × 10−4 M, 85 cm3) to deliver a 10/1 Au/Ni mol ratio, post-treatment as above. Monometallic (HL, 1 mol% and LL, 0.1 mol%) Au/Al2O3 and (LL, 0.1 mol%) Au/TiO2 were prepared by standard impregnation with aqueous HAvCl4 (Aldrich, 7 × 10−4–7 × 10−3 M, 85 cm3). Bulk metal loading was determined by ICP-OES (Vista-PRO, Varian Inc.). The Au-containing samples were stored under He in the dark at 277 K to avoid the deleterious effects of light (photodecomposition of cationic gold to Au0)11 and temperature (aggregation of Au precursor species). Before reaction, the catalyst precursors were activated in 60 cm3 min−1 H2 at 2 K min−1 to 723 K (Ni/Al2O3 and Ni/TiO2) or 603 K (Au/Al2O3, Au/TiO2, Ni–Au/Al2O3, Ni–Au/TiO2), which was maintained for 1 h.

2.2 Catalyst characterisation

Specific surface area (SSA) and total pore volume measurements were made on a Micromeritics Flowsorb II 2300 unit. Prior to analysis, the samples were outgassed at 423 K for 1 h in 20 cm3 min−1 N2. SSA was obtained in a 30% v/v N2/He flow (20 cm3 min−1) with at least three cycles of N2 adsorption-desorption using the standard single-point BET method. Total pore volume was obtained at a relative N2 pressure (P/P0) = 0.95. The data were reproducible to ±3% and values quoted in this paper are the mean.

Temperature programmed reduction (TPR), H2 chemisorption and temperature programmed desorption (TPD) were determined using the CHEM-BET 3000 (Quantrachrome) unit. The samples were loaded into a U-shaped Quartz cell (3.76 mm i.d.) and heated in 17 cm3 min−1 5% v/v H2/N2 (Brooks mass flow controlled) to 603 ± 1 K (Au/Al2O3, Au/TiO2, Ni–Au/Al2O3 and Ni–Au/TiO2) or 723 ± 1 K (Ni/Al2O3 and Ni/TiO2) at 2 K min−1. The effluent gas passed through a liquid N2 trap and H2 consumption was monitored by a thermal conductivity detector (TCD) with data acquisition/manipulation using the TPR Win™ software. The reduced samples were maintained at the final temperature in H2 until return to baseline. After the reduction step, the samples were cooled in a He flow and subjected to H2 chemisorption (at ambient temperature) using a pulse (10 µl) titration procedure, as described elsewhere. TPD was conducted in a N2 flow (65 cm3 min−1) at 50 K min−1 to 873 K with an isothermal hold until the signal returned to the baseline. The support alone was subjected to an equivalent TPR and subsequent TPD, which was used to correct for H2 desorption from Al2O3.

Metal particle morphology, size distribution and surface composition were determined by (scanning) transmission electron microscopy using a JEOL JEM-2100F unit operating at an accelerating voltage of 200 kV with resolution to 0.14 nm and an EDAX Genesis XM 4 system 60. Samples were dispersed in 1-butanol by ultrasonic vibration, deposited on a lacey-carbon/Cu grid (200 Mesh) and dried at 383 K. Up to 300 individual metal particles were counted for each catalyst and the surface area-weighted metal diameter (d) was calculated from:

\[
\frac{d}{\sum n_i d_i^3 \sum n_i d_i^2} = \frac{1}{P_0}
\]

where \(n_i\) is the number of particles of diameter \(d_i\).

2.3 Gas phase nitroarene hydrogenation

2.3.1 Materials. The reactants (p-chloronitrobenzene (p-CN) and m-dinitrobenzene (m-DNB), Aldrich, >98%) and solvent (1-butanol, Riedel-de Haén, ≥99.5%) were used as supplied, without further purification.

2.3.2 Catalytic system. Catalytic reactions were carried out under atmospheric pressure, in situ immediately after activation, in a fixed bed vertical continuous flow glass reactor (i.d. = 15 mm) at 573 K. The reactions were conducted under conditions of
negligible heat/mass transport limitations. A preheating zone (layer of borosilicate glass beads) ensured that the nitroarene reactant was vaporised and reached reaction temperature before contacting the catalyst. Isothermal conditions (+1 K) were maintained by thoroughly mixing the catalyst with ground glass (75 μm) before insertion into the reactor. Temperature was continuously monitored by a thermocouple inserted in a thermowell within the catalyst bed. The p-CNB (or m-DNB) reactant was delivered, in a co-current flow of H₂ via a glass/tetlen air-tight syringe and a teflon line, using a microprocessor controlled infusion pump (Model 100 kd Scientific) at a fixed calibrated flow rate, with an inlet –NO₂ molar flow \((F_{\text{NO}_2})\) in the range 1.1 \(\times\) \(10^{-3}\)–3.1 \(\times\) \(10^{-4}\) mol h\(^{-1}\), where the molar metal to inlet –NO₂ feed rate ratio spanned the range 1.1 \(\times\) \(10^{-3}\)–16.0 \(\times\) \(10^{-3}\) h. The H₂ content was far in excess of the stoichiometric requirement for –NO₂ reduction (160–430), the flow rate of which was monitored using a Humonics (Model 520) digital flowmeter; GHSV = 2 \(\times\) \(10^{3}\) h\(^{-1}\). In a series of blank tests, passage of p-CNB or m-DNB in a stream of H₂ through the empty reactor or over the supports alone did not result in any detectable conversion.

2.3.3 Analytical method and activity/selectionivity evaluation.

The reactor effluent was frozen in a liquid nitrogen trap for subsequent analysis using a Perkin-Elmer Auto System XL gas chromatograph equipped with a programmed split/splitless injector and a flame ionization detector, employing a DB-1 0.20 mm i.d., 0.33 μm film thickness capillary column (J&W Scientific). Repeated catalytic runs with different samples from the same batch of catalyst delivered product compositions that were reproducible to within ±6% with a carbon balance of ±5%. Catalyst activity is quantified in terms of nitroarene (m-DNB) \(X_{\text{m-DNB}}\) or p-CNB \(X_{\text{p-CNB}}\) fractional conversion

\[
X_{\text{nitroarene}} = \frac{[\text{nitroarene}]_{\text{in}} - [\text{nitroarene}]_{\text{out}}}{[\text{nitroarene}]_{\text{in}}} \quad (2)
\]

where the subscripts “in” and “out” refer to inlet and outlet streams, respectively. Selectivity in terms of (e.g.) m-phenylenediamine (m-PDM) from m-DNB \(S_{\text{m-PDM}}\) is given by

\[
S_{\text{m-PDM}} = \frac{[\text{m-PDM}]_{\text{out}}}{[\text{m-DNB}]_{\text{in}} - [\text{m-DNB}]_{\text{out}}} \times 100 \quad (3)
\]

3. Results and discussion

3.1 Catalyst characterisation

The metal content, specific surface area (SSA), pore volume, \(H_{\text{2}}\) uptake/release during TPR/TPD and mean metal particle size for the (mono- and bi-metallic) catalysts used in this study are given in Table 1. The SSA and pore volume of the Al₂O₃ support (191 m² g\(^{-1}\); 450 \(\times\) \(10^{-3}\) cm³ g\(^{-1}\)) are close to values reported for commercial Puralox mesoporous γ-Al₂O₃ (157 m² g\(^{-1}\); 420 \(\times\) \(10^{-3}\) cm³ g\(^{-1}\))\(^{25}\). Incorporation of Au and Ni resulted in a measurable decrease in SSA and pore volume that can be ascribed to partial pore filling by the metal(s) or Al₂O₃ dissolution during impregnation resulting in pore collapse.\(^{26}\) The TiO₂ supported systems exhibited similar SSA and pore volumes to the starting support (52 m² g\(^{-1}\); 120 \(\times\) \(10^{-3}\) cm³ g\(^{-1}\)).\(^{27}\)

The TPR profiles generated for Au/Al₂O₃-HL (I), Au/Al₂O₃-LL (II) and Au/TiO₂-LL (III) can be compared in Fig. 1. The three samples present a principal \(H_{\text{2}}\) consumption peak with an
associated temperature maximum ($T_{\text{max}}$) over 383–434 K, which is within the range recorded elsewhere (328–465 K) for the activation of Au/Al$_2$O$_3$ and Au/TiO$_2$ and attributed to precursor reduction. The lower $T_{\text{max}}$ recorded for Au/TiO$_2$-LL (relative to Au/Al$_2$O$_3$) is consistent with the literature. Delannoy et al. have demonstrated (by in situ XAFS and DRIFTS) greater reducibility of cationic gold on TiO$_2$ compared with Al$_2$O$_3$. Hydrogen consumption during catalyst activation was close to that required for Au$^{3+}$ reduction (Table 1). Supported bimetallic catalyst preparation involved reductive deposition where Ni with a lower electrochemical potential (ECP = −0.27) acts to reduce the Au precursor (HAuCl$_4$, ECP = 1.00). The TPR profiles generated for Al$_2$O$_3$ and TiO$_2$ supported Ni (not shown) exhibited a single broad H$_2$ consumption peak at the final isothermal hold (723 K) that can be associated with a combined decomposition-reduction of the precursor to metallic nickel, as noted elsewhere. A single stage reduction was observed for the supported Ni–Au systems at a higher $T_{\text{max}}$ (414–470 K) than that recorded for the corresponding monometallic Au catalysts. Modification to the TPR response for Au containing bimetallic catalysts with respect to monometallic counterparts has been reported and linked to interaction between both metals. Pu et al. have recently described a stabilisation of Au species (on activated carbon spheres) with the introduction of Ni by co-impregnation that inhibited reduction, displacing the temperature for Au$^{3+}$ → Au$^{0}$ (from 583 K to 588 K) and Au$^{1+}$ → Au$^{0}$ (from 619 K to 659 K) to higher values.

Gold particle size, from TEM analysis (Fig. 2 and 3 and Table 1), is dependent on metal loading and the nature of the support. The particle size in Au/Al$_2$O$_3$-HL was in the range 1–20 nm (Fig. 3(I)) with a surface area weighted mean diameter of 9 nm. The lower Au loaded sample (Au/Al$_2$O$_3$-LL) exhibited a narrower size distribution (1–8 nm, Fig. 3(II)) and smaller mean (4 nm). This effect is consistent with literature that has shown wider size range and the formation of larger nanoparticles with increasing Au content. This can be linked to mobility of the chloride precursor, resulting in Au agglomeration during thermal treatment. Enhanced Au dispersion on TiO$_2$ (Fig. 3(III)) is a consequence of a difference in metal/support interaction relative to Au/Al$_2$O$_3$. Loss of lattice oxygen with the formation of surface vacancies is a feature of thermal treatment in H$_2$ for reducible oxides such as TiO$_2$ at $T \geq 573$ K. These surface defects act as Au nucleation sites with electronic interactions that limit particle growth, leading to enhanced dispersion.

Representative (S)TEM images of Ni–Au/Al$_2$O$_3$-HL (I), Ni–Au/Al$_2$O$_3$-LL (III) and Ni–Au/TiO$_2$-LL (IV) can be compared in Fig. 4. The metal size range in Ni–Au/Al$_2$O$_3$-HL (1–20 nm) coincided with Au/Al$_2$O$_3$-HL and there was no obvious alteration due the inclusion of Ni. This response extended to Ni–Au/Al$_2$O$_3$-LL and Ni–Au/TiO$_2$-LL with an equivalent mean metal size relative to the monometallic system (see Table 1). This can be attributed to the low Ni content in the bimetallic samples. An unchanged metal particle size has been reported previously for TiO$_2$ supported Au and Pt–Au with low Pt content (0.01–0.03 wt%). EDX mapping (see representative analysis for Ni–Au/Al$_2$O$_3$-HL in Fig. 4(II)) demonstrated that individual particles contained both Au and Ni in proportions close to the bulk value (Au/Ni = 10).

EDX analysis cannot establish unequivocally the exact nature of Ni–Au interaction or rule out the occurrence of bimetallic clusters or surface alloy. Both possibilities have been suggested.
for Ni–Au catalysts prepared in an analogous manner and with a similar metal dispersion to that in this study,

Deghedi and co-workers proposed the formation of Ni particles covered with Au adatoms (on the basis of EXAFS and TEM-EDX measurements) for Ni–Au/SiO2 synthesised by redox deposition that contained metal ensembles of 5.1 nm. Maniecki and co-workers reported an alloy phase (on the basis of XRD) for Ni–Au/Al2O3 prepared by co-impregnation (with Ni(NO3)2 and HAuCl4) and reduction in H2. Surface alloy formation was suggested by EXAFS/XANES for Au–Ni/MgAlO4 (10.1 nm) prepared by redox deposition. Molenbroek and Nørskov also demonstrated the occurrence of a surface alloy in Ni–Au/SiO2 (2.5–6.0 nm) and Ni–Au/MgAl2O4 (3.0–15.0 nm) by Monte Carlo simulations, which was experimentally verified by EXAFS, TEM and in situ XRD.

The hydrogenation of nitroarenes is enhanced by contributions due to spillover hydrogen. The generation of spillover species involves dissociative adsorption of H2 on a (donor) supported metal site with migration of the atomic hydrogen generated to the (acceptor) support. Hydrogen TPD is a practical approach to (II) EDX mapping with the associated Ni (counts × 10) and Au distribution, (III) Ni–Au/Al2O3-LL and (IV) Ni–Au/TiO2-LL.

Fig. 4 Representative TEM/STEM images of (I) Ni–Au/Al2O3-LL showing (1) 12 nm and (2) 8 nm segments across individual metal particles subjected to (II) EDX mapping with the associated Ni (counts × 10) and Au distribution, (III) Ni–Au/Al2O3-LL and (IV) Ni–Au/TiO2-LL.

suggests the release of spillover hydrogen generated during catalyst activation by TPR. The shift in the TPD peak for TiO2 systems to a lower temperature (by up to a 100 K) is indicative of a less energetically demanding desorption of H2. This is consistent with literature that has reported a down-shift (by ca. 60–70 K) in the H2-TPD peak for Ni/TiO2 and Pd–Au/Al2O3–TiO2 compared with Ni/Al2O3 and Pd–Al2O3, respectively. Taking the three monometallic Au catalysts presented in Fig. 5, H2 desorbed (Table 1) increased in the order: Au/Al2O3-HL (I) < Au/Al2O3-LL (II) < Au/TiO2-LL (III) where the values obtained are close (54–932 mmol molAu–1) to those reported elsewhere for Au with similar metal size (3–5 nm) supported on Fe2O3.

This sequence reflects that of decreasing mean Au nanoparticle size (Table 1). There is evidence in the literature that metal size is a crucial variable controlling spillover where a greater (donor) surface area for smaller metal nanoparticles extends the donor/acceptor interface and facilitates spillover transfer. The profiles generated for the bimetallic Ni–Au catalysts (Fig. 5, profiles IV–VI) reveals a significant increase in H2 desorbed relative to Au samples with the same loading (see Table 1). This suggests a surface Ni/Au synergism that impacts on H2 adsorption/desorption dynamics. The existing literature on Au containing bimetallics for hydrogenation applications has been from the perspective of Au as a diluent with low H2 uptake capacity and a resultant decrease in surface hydrogen associated with the bimetallic. As a result, there is no directly comparable H2 TPD analysis for supported bimetallic Au-containing systems where the second metal was present in small amounts. We should flag the work of Wojcieszak et al. who observed an increase in H2 released (0.22 → 0.38 mol g–1) during TPD of Ni–Ag/SiO2 with increasing Ni content (0.50 → 0.75 wt%). It is important to note that Ni–Au/Al2O3-HL with lower metal dispersion showed significantly greater H2 desorption (Table 1) relative to Ni–Au/Al2O3-LL. STEM-EDX analyses have demonstrated the presence
of both metals on individual nanoparticles. The formation of bimetallic nano-crystals (i.e. Au decorating Ni nanoparticles) has been demonstrated (EXAFS and TEM-EDS) for Ni–Au bimetallics prepared and activated using a similar methodology. It is known that H2 interaction is distinct for monometallic, bimetallic and alloy nanoparticles. The greater Ni loading in Ni–Au/Al2O3-HL (0.1 mol% vs. 0.01 mol%) must facilitate H2 dissociative adsorption and spillover during TPR, which is reflected in greater H2 release during TPD. In the case of the low loading bimetallics, H2 desorption from Ni–Au/Al2O3-LL exceeded Ni–Au/TiO2-LL (Table 1). This can be tentatively linked to modifications induced by the support that impact on H2 uptake on the bimetallic phase. Likewise, Gu et al. observed a greater H2 TPD from Pd–Au/Al2O3 relative to Pd–Au/Al2O3–TiO2. The characterisation analysis has established the formation of nano-scale (mean = 3–9 nm) Au particles in the monometallics with greater surface hydrogen for catalysts with increasing metal dispersion. TPR measurements suggest interaction of Ni with Au in the bimetallics. STEM-EDX analysis has demonstrated the presence of Au and Ni in individual nanoparticles and the TPD results are consistent with increased spillover resulting from Au/Ni synergy that increases the available surface hydrogen.

3.2 Gas phase nitroarene hydrogenation

The hydrogenation of p-CNB and m-DNB over all the catalysts delivered time-invariant conversions (not shown) and exclusive nitro-group reduction with no evidence of hydrodechlorination, hydrodenitrogenation or aromatic ring reduction. This combined stability/selectivity is important in terms of the viable application of Au catalyst formulations in the production of functionalised anilines. Catalyst deactivation in hydrogenation (of naphthalene, 1,3-butadiene and acetylene) has been reported for Au supported on Al2O3 and TiO2 and ascribed to metal sintering and coking. Moreover, temporal loss of activity in the gas phase hydrogenation of nitroarenes over Pd/Al2O3 has been observed and linked to coke formation.

The applicability of pseudo-first order kinetics for the gas phase hydrogenation of p-CNB and m-DNB has been established elsewhere. The extracted specific (per mol metal) pseudo-first order rate constants (k) are given in Table 2. The promoting effect of Ni is demonstrated by the significantly increased hydrogenation rate when compared with the monometallic Au catalysts with the same loading. Under the same reaction conditions, Ni/Al2O3 and Ni/TiO2 delivered negligible activity. Duan and co-workers using unsupported nano-crystals reported increased rate (mol product mol metal−1 h−1) in the high pressure (40 atm) liquid phase hydrogenation of phenol and benzene over Ni-Rh relative to Rh, which was attributed to the bimetallic character of the nanoparticles (based on HRTEM-EDX and XRD) and possible modifications in active site electron density. Lu et al. recorded higher activity in the liquid phase hydrogenation of a series of p-substituted nitro-derivatives over Ni–Pd colloids, ascribed to the formation of a Ni enriched alloy (from XRD, EXAFS, XPS). The elevated rate observed in this study can be linked to surface available reactive hydrogen as shown in Fig. 6 where H2-TPD is related to the rate constant.

The increase in surface hydrogen that results from incorporation of Ni with Au was accompanied by a higher hydrogenation rate. Moreover, reaction of m-DNB uniformly generated greater rates, a result that can be attributed to the activating effect of the second –NO2 group, which is consistent with a nucleophilic mechanism, as demonstrated previously.

Reaction selectivity is compared at the same degree of conversion in Table 2. p-CNB was converted solely to the target (p-chloroaniline) p-CAN over all the catalysts, which is consistent with reaction exclusivity in continuous gas phase p-CNB over oxide supported Au. In contrast, nitrobenzene, aniline and benzene have been observed in the gas phase hydrogenation of CNB over Ru and Pd catalysts. Variations in product distribution are, however, evident in the hydrogenation of m-DNB and sensitive to the nature of the catalyst. Full selectivity to partially reduced (m-nitroaniline) m-NAN was obtained over monometallic Au systems. In batch liquid phase operation, high pressures (26–34 atm) have been deemed essential to achieve high selectivity (84–98%) to m-NAN. Preferential –NO2 activation on oxide supported Au in the presence of other

For 1 h, T = 573 K

Fig. 6 Variation in hydrogen TPD (H2-TPD) with pseudo-first order rate constant (k) for the hydrogenation of p-CNB and m-DNB over supported Au (open symbols) and Ni–Au (solid symbols) catalysts.
reactive (C=C, carbonyl, amide and ester) functional groups has been demonstrated by FTIR analysis. The incorporation of Ni at low loading (Ni–Au/Al₂O₃-L) served to increase rate while retaining 100% selective to m-NAN. Deghedi et al. reported that the combination of Au and Ni on SiO₂ (Ni: Au molar ratio = 4:1) lowered the rate of C=C bond and aromatic ring hydrogenation relative to Ni in the conversion of styrene, which was accounted for in terms of geometric and electronic effects. At higher loadings (Ni–Au/Al₂O₃-HL) complete hydrogenation relative to Ni in the conversion of styrene, that acts in tandem with differences in available reactive hydrogen. This may be a consequence of increased surface reactive hydrogen which facilitates reduction of both –NO₂ substituents. Alternatively, m-DNB activation on Ni-Au/Al₂O₃-HL may be distinct from Ni–Au/Al₂O₃-LL with a planar adsorption on the former through the aromatic ring, resulting in the formation of a resonance structure with two positive localised charges where both –NO₂ groups are activated for nucleophilic attack. It is known that substituted aromatics interact with supported Ni catalysts via the π electron-delocalised aromatic ring. Lonergan et al. have observed n-butane selectivity effects in 1,3-butadiene hydrogenation over Ni-Pt/Al₂O₃ with increasing Ni content (1:3 → 1:10). The formation of m-PDM was also promoted over Ni–Au/TiO₂-LL, which suggests a support effect in terms of m-DNB adsorption/activation that acts in tandem with differences in available reactive hydrogen. Wang et al. reported a modified catalytic response in the hydrogenation of 1,3-butadiene for Pr–Ni on Al₂O₃ and TiO₂. DFT calculations revealed stronger metal interaction with Al₂O₃ (binding energy ca. –50 kcal mol⁻¹) than TiO₂ (–17 kcal mol⁻¹) with a preferential Ni-Al₂O₃ interaction at the metal-support interface leading to a Pt-terminated bimetallic configuration. A weaker Ni interaction in the case of the TiO₂ carrier can then result in some segregation of the Ni component to the nanoparticle surface.

4. Conclusions

Oxide (Al₂O₃ and TiO₂) supported Au (1 and 0.1 mol%) prepared by impregnation with subsequent activation generated nano-scale metal particles of mean size 3–9 nm. A decrease in Au size was accompanied by increased surface hydrogen (from TPD analysis) with higher specific chemoselective hydrogenation rate in the conversion of p-CNB → p-CAN and m-DNB → m-NAN. Supported bimetallic synthesis by reductive deposition of Au on Ni (where Au/Ni = 10) generated an equivalent particle size at the same Au loading but elevates the available surface hydrogen with a significant increase in –NO₂ group reduction rate. TPR analysis suggests Ni–Au interaction where (S)TEM-EDX mapping across isolated single particles has established Au and Ni in close proximity with a surface Au/Ni that coincided with the bulk value. Reaction of p-CNB over the bimetals delivered full selectivity to p-CAN. Conversion of m-DNB was fully selective to m-NAN over monometallic Au and Ni–Au/Al₂O₃-LL. The hydrogenation of both –NO₂ substituents (to m-PDM) was promoted over Ni–Au/Al₂O₃-HL and Ni–Au/TiO₂-LL. This is attributed to the higher Ni loading that elevated the surface supply of hydrogen and possible electronic/geometric modifications induced by the support that impact on the m-DNB adsorption/activation. We have demonstrated Au/Ni synergy that serves to enhance –NO₂ reduction rate.
