α-Na₃NpO₄ and α-Na₃PuO₄ exhibit an orthorhombic structure (Z = 8), in space group Pnmm, with lattice parameters $a = 13.352(2)$ Å, $b = 9.634(2)$ Å, and $c = 6.651(2)$ Å for the neptunium compound, and $a = 13.302(2)$ Å, $b = 9.634(2)$ Å, and $c = 6.651(2)$ Å for the plutonium analogue. The corresponding structure has been solved ab initio as no structural analogue could be found in the literature. The pentavalent state of neptunium has moreover been confirmed by $^{237}$Np Mössbauer spectroscopy, and the local structural properties inferred from the X-ray Rietveld refinement have been related to the fitted quadrupole coupling constant and asymmetry parameters. The existence of a low temperature metastable m phase of Na₃NpO₄ and Na₃PuO₄, of the NaCl type, has also been suggested.

1. Introduction

The long-term storage of high-level radioactive waste, especially of the long lived actinides (Np, Am, Cm) generated during the irradiation process in conventional nuclear reactors, is a subject of primary concern for the nuclear industry with respect to the public. One solution to reduce the waste’s radiotoxic inventory is to recover the long-lived isotopes from the spent fuel and re-irradiate them in a fast reactor to transmute them into less radioactive elements with shorter half-lives. Operating in a closed fuel cycle and with a fast neutron spectrum, Sodium-cooled Fast Reactors (SFR) are currently considered as one of the most advanced options in terms of management of the actinides.3,4 Moreover, SFRs present appealing advantages over the current second generation reactors, especially because of their improved energy efficiency. The sodium metallic coolant allows a significant margin to overheating due to its high heat capacity, and its boiling point (1156 K) which is much higher than the reactor’s operating temperature.

A safety concern for these reactors comes, however, from the potential interaction of the (U, Pu)O₂ mixed oxide fuel with the metallic sodium coolant in the event of a breach of the stainless steel cladding. The reaction between sodium and uranium-plutonia solid solution leads to the formation of Na₄(U, Pu)O₄, a compound with lower density and thermal conductivity than the mixed oxide fuel.5–7 The introduction of minor actinides into the fuel, i.e. (U, Np, Pu, Am)O₂, will introduce a much more complex chemistry for which many data are still missing.

Keller and coworkers pioneered the study of the interaction between minor actinides (Np, Am) and alkali metals.8,9 As part of our program of research, we have recently revisited the structural properties of the Na–Np–O10,11 and Na–Pu–O systems,12 and confirmed the formation of the hexavalent and heptavalent compounds Na₅NpO₆, Na₃AnO₅ (An = Np, Pu), and Na₅AnO₆ (An = Np, Pu). The present study focuses on the pentavalent composition Na₃AnO₄, as this product is more likely to form under the oxygen potential conditions of the reactor.

Keller et al. reported in 1965 the existence of Na₅AnO₄ (An = Np, Pu, Am). They suggested Na₃AmO₄ had a pure NaCl type of structure with cell parameter $a = 4.75$ Å, while Na₅NpO₄ and Na₅PuO₄ adopted a NaCl-type superlattice structure.9,13,14 The cell parameters for Na₅PuO₄ were reported as $a = 4.88$ Å13 and $a = 4.86$ Å.16 In 1989, Pillon suggested for the same compound indexing on the basis of a rhombohedral lattice with
$a = 4.678 \text{ Å}$ and $a = 60.40^\circ$, as well as the existence of two phase transitions for this compound at 623 K and 1048 K, respectively. The literature is quite confusing with respect to the Na$_3$AnO$_4$ (An = Np, Pu, Am) composition, and a detailed crystal structure analysis is lacking. The ionic radii of pentavalent uranium, neptunium, and plutonium being very close (0.76, 0.75 and 0.74 Å, respectively, for 6-fold coordination), one could expect the corresponding Na$_3$AnO$_4$ structures to be similar. There are some indications in the reported data that this is not the case, however.

In the present work, the structures of $\alpha$-Na$_3$NpO$_4$ and $\alpha$-Na$_3$PuO$_4$ have been solved using room temperature X-ray diffraction. The pentavalent state of the neptunium cation has moreover been confirmed by $^{237}$Np Mössbauer spectroscopy, and the local structural properties inferred from the X-ray refinement have been related to the fitted Mössbauer parameters, i.e. quadrupole coupling constant and asymmetry parameters. The existence of a low temperature cubic phase of Na$_3$NpO$_4$ and Na$_3$PuO$_4$ has finally been revealed.

2. Experimental section

2.1. Raw materials and solid state synthesis

$\alpha$-Na$_3$NpO$_4$ was prepared by grinding together neptunium dioxide ($^{237}$NpO$_2$ from ORNL, Oak Ridge) with sodium oxide (Na$_2$O 82.1%, Na$_2$O$_2$ 14.8%, ABCR GmbH & Co, i.e. Na$_2$O$_{1.14(1)}$) in a (NpO$_2$ : Na$_2$O$_{1.14(1)}$) = (1 : 2.4) ratio in an argon filled dry glove box. Sodium oxide was carefully stored in the dry atmosphere of the glove box because of its hygroscopic nature. The (NpO$_2$ : Na$_2$O$_{1.14(1)}$) mixture was introduced into a stainless steel container that was tightly closed under the purified argon atmosphere of the glove box, and heated in a tubular furnace at 1123 K for 24 hours. No secondary phases were detected by X-ray diffraction, and the prepared sample was subsequently used for the Mössbauer measurement (section 4).

The existence of a metastable cubic disordered phase of Na$_3$NpO$_4$ (m phase) was also investigated by mixing neptunium dioxide with sodium oxide in the same (1 : 2.4) ratio, and heating the mixture for 12 hours under argon flow at successively 673 and 873 K. The latter material was also measured by Mössbauer spectroscopy, as detailed in section 5.

The application of the aforementioned synthesis route to plutonium dioxide ($^{239}$PuO$_2$ from ITU-JRC stocks) did not lead to the formation of $\alpha$-Na$_3$PuO$_4$, but to Na$_2$PuO$_4$ which is a monoclinic phase, in space group C2/c. $\alpha$-Na$_3$PuO$_4$ was nevertheless obtained by mixing plutonium dioxide with sodium carbonate (Na$_2$CO$_3$ 99.95%, Sigma) in a (1 : 2) ratio, and heating the mixture under a flow of argon in a tubular furnace at 1093 K for 80 hours with intermediate regrinding steps. The $\alpha$-Na$_3$NpO$_4$ phase was also obtained with this method, but with small admixtures of Na$_3$NpO$_4$ and unreacted NpO$_2$. The latter material was used for the high temperature X-ray diffraction study reported in the ESL.

2.2. Powder X-ray diffraction

The samples were characterized at room temperature by X-ray diffraction using a Bruker D8 X-ray diffractometer mounted in the Bragg–Brentano configuration with a curved Ge monochromator (111), and a ceramic copper tube (40 kV, 40 mA) equipped with a LinXEye position sensitive detector. The data were collected by step scanning in the angle range 10° ≤ 2θ ≤ 120°, with an integration time of about 8 h, a count step of 0.02° (2θ), and a dwell of 5 s per step. Structural analysis was performed by the Rietveld method with the Fullprof2k suite.

2.3. Mössbauer spectroscopy

The $^{237}$Np Mössbauer spectroscopy measurements were carried out in transmission, using an $^{241}$Am metal source with a sinusoidal driving mode. The effect was measured with a photon energy of 59.54 keV. The powder samples, encapsulated in 3 concentric aluminium containers, were probed in the temperature range 4.2–20 K, while the source was kept at a constant temperature of 4.2 K inside an independent chamber in the stainless steel cryostat. The velocity scale was moreover calibrated with respect to NpAl$_2$.

3. Structural refinement

3.1. $\alpha$-Na$_3$NpO$_4$

A brand new phase, for which there is no report in the literature and no structural analogue, was synthesized by reaction at 1123 K between neptunium dioxide and sodium oxide as described in the Experimental section (Fig. 1).

An orthorhombic cell, in space group Fmmm (No. 69), was determined using the program NITREOR implemented in EXP02013. The crystallographic structure was then solved by the heavy-atom method, which consists in determining first the position of the heaviest atoms in the compound (here neptunium). This technique is particularly well suited for compounds containing both heavy atoms and much lighter ones, as in the present case. Based on the volume of the unit cell (858.1 Å$^3$), only eight Na$_3$NpO$_4$ molecules can reasonably fit. Besides, only nine Wyckoff positions are possible for the Fmmm space group: two with a multiplicity of 4, six with a multiplicity of 8, and one with a multiplicity of 16. Accordingly, various combinations were tested, taking into account that only 8 neptunium atoms should be found in the unit cell.

Eventually, one neptunium on the Wyckoff position (8g), i.e. (x, 0, 0), reproduced reasonably well the experimental X-ray diffraction pattern with an arbitrary value for the fractional coordinate x = 0.1. The latter value was refined by Rietveld analysis. The positions of the lighter atoms – Na and O – were subsequently determined by 3D Fourier differences (using the program GFourier (Version 04.06) of the Fullprof2k suite), which show the residual electronic density in the unit cell. The final atomic positions were refined by the Rietveld method.

The cell parameters were determined as $a = 13.353(2)$ Å, $b = 9.629(2)$ Å, and $c = 6.673(2)$ Å. Refined atomic positions are listed in Table 1.
Na$_3$NpO$_4$ is suggested to form according to the probable reaction (1). The sodium peroxide impurity present in the commercial sodium oxide starting material is acting as an oxidizing agent allowing the formation of this new pentavalent phase.

$$\text{Na}_2\text{O}_2(\text{s}) + 2.064\text{Na}_2\text{O}(\text{s}) + 0.336\text{Na}_2\text{O}_2(\text{s}) \rightarrow \text{Na}_3\text{NpO}_4(\text{s}) + 1.8\text{Na}(\text{g}) + 0.368\text{O}_2(\text{g})$$  \hspace{1cm} (1)

The structure is made of distorted NpO$_6$ octahedra with minimum and maximum bond lengths 2.066(6) and 2.417(6) Å, respectively (Table 2). The O(3)--Np--O(3) bond, pointing along the $b$ direction, is not strictly linear, but has an angle of 179.0°, while the O(1)--Np--O(2) bonds in the equatorial plane form angles of 177.0°. The distortion is also pronounced in the NaO$_6$ octahedra (from 2.267(8) to 2.756(6) Å). As shown in Fig. 2, the NpO$_6$ octahedra are connected to each other via one edge and two corners in the (ac) plane, and form layers perpendicular to the $b$ direction. The Na1 atoms are located within the layers, while the Na2 and Na3 atoms are located in between the layers and bind them together. Na2 and Na3 alternate in rows along the $c$ direction.

3.2. α-Na₃PuO₄

α-Na₃PuO₄ is isostructural with its neptunium analogue. The refinement yielded in this case lattice parameters as \( a = 13.302 \) Å, \( b = 9.634(2) \) Å, and \( c = 6.651(2) \) Å. The unit cell volumes of the neptunium (838.1 Å³) and plutonium (852.3 Å³) compounds are consistent with the ionic radii of Np⁵⁺ and Pu⁵⁺ (0.75 and 0.74 Å, respectively)\(^{18}\). The refined atomic positions are presented in Table 3. The corresponding distances and angles are listed in Table 2. The X-ray diffraction pattern is shown in Fig. 3.

3.3. The Na₃AnO₄ structure along the series of the actinide elements (An = U, Np, Pu)

The mean Np–O distance, obtained after refinement of the Na₃NpO₄ structure, is consistent with the ones obtained for hexavalent (Na₃NpO₄, Na₃NpO₅, Na₃Np₂O₇) and heptavalent (Na₃NpO₆) sodium neptunate compositions\(^{10}\), where neptunium is also 6-fold coordinated. As shown in Fig. 4, this distance decreases when the valence state of neptunium increases. The same trend is verified for the 6-fold coordinated PuO₆ octahedra. The mean Pu–O distance in Na₃PuO₄ (2.33(2) Å) is moreover consistent with the one reported for pentavalent Na₃UO₄ phase (2.15 Å). However, we did not succeed in synthesizing this phase either with sodium oxide or sodium carbonate, suggesting that orthorhombic Na₃UO₄ cannot form as a stable phase. The compound adopts instead a monoclinic or cubic phase, with mixed valence state composition Na₃(U₁ₓNa₀.₈₄(2)Na₀.₁₆(2))O₄, where x is 0.68(3), indicating a lower symmetry than the mean U–O distance around 2.18(1) Å.

Although the ionic radii of Np⁵⁺ and Pu⁵⁺ are very close (0.75 and 0.74 Å, respectively, in 6-fold coordination) to that of U⁵⁺ (0.76 Å)\(^{16}\), the Na₃NpO₄ and Na₃PuO₄ structures differ from the corresponding phase of uranium. The structure of the trisodium uranate Na₃(U₁₋ₓNaₓ)O₄ (0 < x < 0.16(2)) was recently investigated\(^{21}\) and shown to exhibit three polymorphs: a low temperature metastable NaCl type of structure (m phase), a stable α monoclinic phase, in space group \( P2₁ \), and a high temperature β cubic phase, in space group \( Fd3m \).\(^{21}\) It was also shown that the α phase can accommodate excess sodium on the uranium site up to the composition Na₃(U₀.₈₄(2)Na₀.₁₆(2))O₄. The charge balance is then realized by the uranium cation, which adopts a mixed valence state with (76 ± 12%) \( U^{VI} \) and (24 ± 12%) \( U^{V} \).

Following the trend shown in Fig. 4, one would expect an orthorhombic \( α-Na₃U^{V}O₄ \) phase with a mean U–O distance around 2.23 Å, i.e. slightly higher than the mean U–O distance in pentavalent Na₃U(V)O₃ compound (2.15 Å). However, we did not succeed in synthesizing this phase either with sodium oxide or sodium carbonate, suggesting that orthorhombic Na₃UO₄ cannot form as a stable phase. The compound adopts instead a monoclinic or cubic phase, with mixed valence state composition Na₃(U₁₋ₓNaₓ)O₄ (0 < x < 0.16(2)), and a mean U–O distance around 2.18(1) Å.

</table>

\( a \) The rather large value of \( R_{\text{wp}} \) is related to the experimental constraints for the plutonium compound: small amount of material, and encapsulation for the X-ray measurement in glue resulting in a high background level and rather poor signal to background ratio.

4. Mössbauer spectroscopy studies of α-Na₃NpO₄

The Mössbauer spectrum of α-Na₃NpO₄ recorded at 4.2 K is shown in Fig. 5. It consists of a single quadrupolar split pattern centred at \( -17.3 \) mm s\(^{-1} \), which corresponds to an isomer shift of \( \delta_{\text{is}} = -30.9(3) \) mm s\(^{-1} \) relative to the standard NpAl₂ absorber. The latter value lies in the range \( -11.0 < \delta_{\text{is}} < -37.5 \) mm s\(^{-1} \), which confirms the Np\(^{V} \) charge state, corresponding to a \( [\text{Rn}]5f^2 \) electronic configuration, as displayed in the correlation diagram in Fig. 6. The pure Np\(^{V} \) valence state derived herein is a proof that a mechanism of incorporation of Na on the neptunium site (and charge compensation by the neptunium cation) does not occur, by contrast with the uranium phase.\(^{21}\) It is suggested that this is also the case for the plutonium phase, but X-ray Absorption Near-Edge Structure spectroscopy or \( ^{23}\)Na Magic Angle Spinning Nuclear Magnetic Resonance measurements would be needed to confirm this hypothesis.

The spectral shape remains the same between 4.2 and 20 K, except for a slight decrease in overall effect with increasing temperature, which is attributed to the temperature dependence of the Lamb–Mössbauer factor. The occurrence of a phase transition (either crystallographic or magnetic) within the probed temperature range is therefore excluded.

The existence of a quadrupole coupling constant \( |e^2qQ| = 48.6(3) \) mm s\(^{-1} \), and non vanishing asymmetry parameter \( \eta = 0.68(3) \), indicates a lower symmetry than \( O_h \) in α-Na₃NpO₄. These results are in good agreement with the local symmetry around the neptunium ion as determined by X-ray diffraction, \( i.e. \) rather strongly distorted NpO₆ octahedra. It is interesting to compare the quadrupole coupling constant measured here...
with the values for other pentavalent compounds, in particular 
(NpO$_2$)$_2$SO$_4$, 2H$_2$O ($|e^2gQ| = 82.4(1.0)$ mm s$^{-1}$), and 
Na$_4$(NpO$_2$)$_2$C$_{12}$O$_{12}$·8H$_2$O ($|e^2gQ| = 94.0(1.0)$ mm s$^{-1}$). Those 
compounds both present [NpO$_2$]$_2^+$ neptunyl type of ions, i.e. with 
two close oxygen neighbours in the axial direction, which 
leads to much higher values of the quadrupole coupling 
constants (around 100 mm s$^{-1}$). The same observation was made 
for hexavalent phases.\textsuperscript{23}

5. A low temperature metastable 
NaCl type of structure

Literature dating back to the sixties and seventies suggests 
a NaCl type of structure for Na$_3$AnO$_4$ (An = U, Np, Pu,
The existence of such a phase for neptunium was re-investigated in the present work by reaction between neptunium dioxide and sodium oxide at low temperatures (673 K) under argon flow. This led to the formation of a poorly crystallized cubic product \( X \), with cell parameter \( a = 4.746(5) \) Å, similar to the one reported for \( \text{Na}_3\text{AmO}_4 \) \( (a = 4.75 \) Å).\(^9\)

Mössbauer spectroscopy measurements were performed so as to determine the exact oxidation state and chemical composition of product \( X \). Under the assumption that there are no magnetic phases in \( X \), the measured Mössbauer spectrum (Fig. 7) revealed two distinct sites (A and B) with isomer shifts (with respect to NpAl\(_2\)) at \( \delta_{\text{IS,A}} = -32.2(3) \) mm s\(^{-1}\) (47.5% for A) and \( \delta_{\text{IS,B}} = -52.7(3) \) mm s\(^{-1}\) (52.5% for B), corresponding to Np(V) and Np(VI), respectively. The existence of two valence states shows there must be oxygen vacancies within the lattice and explains the observed disordered structure of product \( X \). The local symmetry is therefore not perfectly cubic. The shape of the experimental spectrum is adequately described by taking into account that the quadrupolar interactions acting at both A and B sites are distributed. Symmetric distributions of the quadrupole coupling constants around their mean values \( |\varepsilon^2Q_A| = 67.2(5) \) mm s\(^{-1}\) and \( |\varepsilon^2Q_B| = 36.2(5) \) mm s\(^{-1}\) are assumed. The standard deviations of the distributions are found to be \( \sigma_{A,B} = 18.7 \) mm s\(^{-1}\).

Under those synthesis conditions, one can reasonably expect to form tetravalent (Na\(_2\)NpO\(_3\)), pentavalent (Na\(_3\)NpO\(_4\)), or hexavalent (Na\(_4\)NpO\(_5\)) compounds, which can be written with the more general formula Na\(_{1-x}\)Np\(_x\)O with \( x = \{1/5–1/3\} \). The synthesized product \( X \), with an average valence of 5.525, corresponds to the chemical composition Na\(_{0.779}\)Np\(_{0.221}\)O or Na\(_{3.525}\)Np\(_{4.525}\), according to the ratio of the relative areas of the sub-spectra of Np(V) and Np(VI). There again, the sodium peroxide impurity present in the starting synthesis materials is acting as an oxidizing agent during the solid state reaction. The final product corresponds either to a solid solution between the two end-members m-Na\(_3\)NpO\(_4\) and m-Na\(_4\)NpO\(_5\), or to a mixture of these same phases whose lattice parameters are too close to be distinguished in the present X-ray diffraction pattern showing very broad X-ray reflections. The existence of the m-NaNpO\(_3\) cubic phase was reported in the literature with a cell parameter as 4.739 Å,\(^8\) but is subject of controversy.\(^14,17\) A more detailed study of the possible reactions products forming at low temperatures (\( T < 873 \) K) depending on the oxygen potential conditions would be needed to clarify this point, and discard one of these two hypotheses.

The compound \( X \) was furthermore heated up to 1473 K under argon flow. The X-ray analysis performed on the sample after cooling down to room temperature revealed β-NaNpO\(_3\) as the major phase, and α-NaNpO\(_3\) as a secondary phase. Supposing that m-NaNpO\(_3\) and m-NaNpO\(_4\) form a solid solution
at low temperatures, the heating treatment up to 1473 K leads to phase separation (demixing) into the two equilibrium phases.

Bykov et al., who recently revisited the Na–Pu–O system, performed an exhaustive study of the various reaction products forming at low temperatures by reaction between plutonium dioxide and sodium oxide. The authors reported the formation, after heating at 673 K for 24 hours under oxygen flow, of a cubic phase of cell parameter \( a = 4.73 \text{ Å} \) (phase c.p. I), when mixing PuO\(_2\) and Na\(_2\)O in \((1:1.8)\), \((1:3.6)\), and \((1:4.8)\) ratios. Under argon flow, the mixing of PuO\(_2\) and Na\(_2\)O in \((1:1.2)\), \((1:1.8)\), \((1:2.4)\), and \((1:3.6)\) ratios, led to the formation of a cubic phase of cell parameter \( a = 4.77 \text{ Å} \) (phase c.p. II). Slow heating of the phase c.p. II up to 1073 K under argon flow moreover led to the formation of \( \alpha-\text{Na}_3\text{PuO}_4 \) together with small unidentified impurities. It is suggested that the phase c.p. I corresponds to Pu\(\text{v}\), while c.p. II is closer to Pu\(\text{v}\). It could be either pure Pu\(\text{v}\), or a mixed valence state compound Pu\(\text{v}\)/Pu\(\text{vi}\) such as product “X”. This is consistent with the smaller ionic radius of Pu\(\text{vi}\) (0.71 Å), compared to Pu\(\text{v}\) (0.74 Å) according to Shannon’s tabulated data.

6. Conclusion

The structures of Na\(_3\)NpO\(_4\) and Na\(_3\)PuO\(_4\) have been determined in the present work for the first time. The compounds were shown to exhibit a completely disordered NaCl type of structure at low temperatures (\( T < 873 \text{ K} \)), corresponding to a metastable \( m \) phase, that transforms to the equilibrium \( \alpha \) phase (with orthorhombic symmetry, in space group \textit{Fmmm}), when heated at higher temperatures (\( T > 1093 \text{ K} \)). The \( \alpha \) structures have been refined by the Rietveld method. The pentavalent state of neptunium has been confirmed from the isomer shift value obtained by Mössbauer spectroscopy, \( |\varepsilon'Q| = 48.6(3) \text{ mm s}^{-1} \), and rather high asymmetry parameter, \( \eta = 0.68(3) \), have been related to the distortion of the NpO\(_6\) octahedra in this structure, which show Np–O bond lengths between 2.066(6) and 2.417(6) Å, and non linear O(3)–Np–O(3) (179.0°) and O(1)–Np–O(2) (177.0°) bonds. Interestingly, Na\(_3\)NpO\(_4\) and Na\(_3\)PuO\(_4\) do not adopt the same monoclinic structure as Na\(_3\)(U\(_{1-x}\)Np\(_x\))O\(_4\) \((0 < x < 0.16(2))\) despite having very close ionic radii. It is suggested that orthorhombic Na\(_3\)UO\(_4\) cannot form as a stable phase.

Acknowledgements

The authors would like to express their gratitude to D. Bouéxière and G. Pagliosa for the collection of room temperature and high temperature X-ray diffraction data. They also thank the \( 7^{th} \) Framework Program of the European Commission, and the Joint Advanced Severe Accidents Modelling and Integration for Na-cooled neutron reactors (JASMIN) program (No. 295803 in FP7). ALS acknowledges the European Commission and the Ras al Khaimah Centre for Advanced Materials for funding her PhD studentship.
