Tin(II)-functionalization of the archetypal $\{P_8W_{48}\}$ polyoxometalate†

N. V. Izarova,*a L. Klaß,a,b P. de Oliveira,c I.-M. Mbomekalle,c V. Peters,b F. Haarmannb and P. Kögerler*a,b

The synthesis of $[K_{4.5} (ClSn^{II})_8 P_8W_{48}O_{184}]^{12.5-}$, featuring Sn(II) ions in trigonal-pyramidal SnO$_2$Cl environment coordinating to the two inner rims of the wheel-shaped ($P_8W_{48}$)-type polyoxometalate(IV) archetype, showcases how high chloride ligand concentrations as well as the control of the polyanion solubility via electrolytes and evaporation rates are essential to prevent numerous competing reactions that can hamper the Sn(II) functionalization of polyoxometalates.

In the complexes of Sn$^{II}$ with $\alpha$-A-isomers of trilacunary Keggin-type POTs or POMs with more complex structures remains unstudied. Therefore we decided to investigate the reaction of Sn$^{II}$ chloride with the archetypal macrocyclic phosphotungstate $[P_3W_{15}O_{50}]^{3-}$ (ref. 7) and the $Sn_3(W_8O_{39})_2$) subunit in the above-mentioned $[Sn_3(SnW_9O_{34})_2]$ complexes as well as act as a linker between the intact paratungstate-B structures leading to anionic clusters $[H_2SnW_{12}O_{42}]^{3-}$. In the complexes of Sn$^{II}$ with $\alpha$-A-isomers of trilacunary Keggin-type POTs or POMs with more complex structures remains unstudied. Therefore we decided to investigate the reaction of Sn$^{II}$ chloride with the archetypal macrocyclic phosphotungstate $[P_3W_{15}O_{50}]^{3-}$ (ref. 7) and the $Sn_3(W_8O_{39})_2$) subunit in the above-mentioned $[Sn_3(SnW_9O_{34})_2]$ complexes as well as act as a linker between the intact paratungstate-B structures leading to anionic clusters $[H_2SnW_{12}O_{42}]^{3-}$. At the same time the reactivity of Sn$^{II}$ towards multi-lacunary (i.e. more reactive) derivatives of Wells–Dawson-type POTs or POMs with more complex structures remains unstudied. Therefore we decided to investigate the reaction of Sn$^{II}$ chloride with the archetypal macrocyclic phosphotungstate $[P_3W_{15}O_{50}]^{3-}$ (ref. 7) and the $Sn_3(W_8O_{39})_2$) subunit in the above-mentioned $[Sn_3(SnW_9O_{34})_2]$ complexes as well as act as a linker between the intact paratungstate-B structures leading to anionic clusters $[H_2SnW_{12}O_{42}]^{3-}$.
\[ \{H_2O\}_{2}^{2-},\quad \{Fe_6(\text{OH})_2(H_2O)\}_{2}^{2+},\quad \{P_2W_6O_{18}O_{18}\}^{2-},^{10b} \quad \{K_{6} \subset \{P_2W_6O_{18}\}_{2}^{2-},^{10c} \quad \text{and others} \} \] can also assume the role of a secondary building block in the carbon-free 3D coordination framework \( K_{13}Li_6[\text{Mn}_{8}(H_2O)_{48}]^{2-}\cdot P_2W_4O_{18} \cdot 108H_2O \), exhibiting rigid cages with an approximate volume of 7.24 nm\(^3\)

Herein we report the first example of a \( \{P_2W_{48}\} \) POT incorporating the main group element, namely the polyanion \( [K_{4.5}Li_{1}]=3 \) that was synthesized in a one-pot reaction in an aqueous medium, isolated as the hydrated potassium/lithium salt \( K_{10}Li_{17.5}[K_{4.5}Li_{1} \subset \{P_2W_{48}\}] \) at room temperature for 4–5 h. Alternatively heating at 50 °C for 1 h, the reaction mixture could be stirred at room temperature for 4–5 h. The large bright-orange block-shaped crystals of \( \text{KLi-1} \) form within several days by the evaporation of the obtained solutions under a hood. During the reaction the color of the reaction mixture changes from bright-orange to brown and then to dark-green indicating partial reduction of W VI centers of mixture changes from bright-orange to brown and then to large bright-orange block-shaped crystals of carbon-free 3D coordination framework \( K_{13}Li_6[\text{Mn}_{8}(H_2O)_{48}]^{2-}\cdot P_2W_4O_{18} \cdot 108H_2O \), exhibiting rigid cages with an approximate volume of 7.24 nm\(^3\).

**Results and discussion**

**Synthesis**

The polyanions \( \text{1} \) have been synthesized by the reaction of \( [H_{2}P_{2}W_{48}O_{18}]^{3-} \) with \( \text{Cl} \) in 4 M aqueous LiCl solution at 50 °C. Alternatively heating at 50 °C for 1 h, the reaction mixture could be stirred at room temperature for 4–5 h. The large bright-orange block-shaped crystals of \( \text{KLi-1} \) form within several days by the evaporation of the obtained solutions under a hood. During the reaction the color of the reaction mixture changes from bright-orange to brown and then to dark-green indicating partial reduction of W VI centers of \( \{P_2W_{48}\} \) by Sn\(^{II}\) to W\(^{VI}\) ions which are then slowly reoxidized by air oxygen. To minimize this undesirable process, lowering the growth rate of the reaction solution also seems to play a crucial role. Thus, evaporation under a fumehood results in the rapid crystallization of \( \text{KLi-1} \) within 1–6 days, while slower evaporation of the reaction mixture (e.g. outside a fumehood) leads to gradual decomposition of \( \text{1} \) with the formation of a white viscous gel-like precipitate. This product most likely represents a mixed Sn\(^{II}\) chloride-hydroxide (Sn(OH)Cl), the formation of which is followed by a visible color change of the reaction mixture, which complicates the isolation of pure \( \text{KLi-1} \). A relatively high Cl\(^{-}\) concentration is also important as it serves as a source of terminal chloride ligands on the Sn\(^{II}\) centers in \( \text{1} \). Thus, the polyanion \( \text{1} \) cannot be crystallized from other media (e.g., \( \text{LiOAc} (\text{pH} \sim 2–6), \text{NaOAc} (\text{pH} \sim 2–6), \text{Li}_{2}SO_{4} (\text{pH} \sim 2–3) \) or 2 M LiCl and NaCl) where the reaction products of \([H_{2}P_{2}W_{48}O_{18}]^{3-}\) with \( \text{Cl} \) turn out to be mixtures of hydrated K\(^{+}/\text{Li}\(^{+}\) salts of polyanions with the general composition \([\text{HOSn}^{II}]_{x}P_{2}W_{48}O_{18}^{y}\) with \( x = 3–6 \)

**Crystal structure analysis**

Compound \( \text{KLi-1} \) crystallizes in tetragonal symmetry in the space group \( I4/m \). The polyanion \( \text{1} \) consists of a macrocyclic phosphotungstate \( \{P_2W_{48}\} \) which is coordinated by eight Sn\(^{II}\) ions that are located in the inner cavity of \( \{P_2W_{48}\} \) at the eight vacant sites between neighboring \( \{P_2W_{48}\} \) subunits. Each Sn\(^{II}\) center binds to two terminal oxygen positions belonging to two adjacent \( \{P_2W_{12}\} \) groups (\( \text{Sn-O} 2.140(10)\sim 2.152(11)\text{Å} \); Fig. 1). Thus, the POM possesses an idealized \( D_{4h} \) symmetry. The bond lengths and angles within the phosphotungstate framework are in the usual range (see Table S1†).

Each Sn\(^{II}\) center resides in a trigonal pyramidal SnO\(_{2}\)Cl coordination environment with a terminal chloride ligand \( \text{Sn-Cl} \) 2.515(6) Å directed towards the center of the \( \{P_2W_{48}\} \) ring. This trigonal-pyramidal coordination mode is reminiscent of several other anionic Sn(\text{i}) complexes such as SnCl\(_{3}\), that are formed in aqueous solutions at higher halide concentrations, or SnCl\(_{2}(H_2O)\). The Sn–Cl bond lengths in \( \text{1} \) can be compared with those of 2.523 and 2.595 Å in \( \text{Cs}[\text{SnCl}_3] \) and \( \text{SnCl}_2(H_2O) \), respectively. The Sn–O and Sn–Cl bond distances in \( \text{1} \) also correlate rather well with the Sn–O bond lengths in \( \text{SnCl}_2(H_2O) \) (2.169 Å)\(^{ab}\) and other Sn\(^{II}\)-containing POTs.\(^{3–8}\) The O–Sn–O and O–Sn–Cl angles are in the usual

![Fig. 1 Structure of 1 in combined polyhedral/ball-and-stick representation. Color legend: WO\(_{6}\), yellow octahedra; Sn, blue; K, light blue; Cl, lime green; O, red spheres. The P centers are not visible in this perspective.](https://example.com/structure.png)
range and constitute 91.5(4)% and 85.8(3)–86.3(3)%, respectively. The lone electron pair on each SnII center is oriented towards the center of the polyanion and thus is sterically inaccessible. The closest Sn···Sn distances are 3.956(1) Å between the SnII centers situated on the opposite side of \{P8W48\} and 7.248(1) Å between the SnII centers located on the same side of the wheel.

The inner cavity of 1 is occupied by four K⁺ countercations each forming weak electrostatic interactions with four oxygen atoms of two phosphate groups of one of the \{P8W48\} units (K-O: 2.815(11)–2.828(11) Å) and four chloride ligands on the adjacent SnII centers (K-Cl: 3.278(8)–3.301(8) Å). In addition, half of the polyanions in the solid-state structure of KLi-1 incorporate a central K⁺ cation, which coordinates eight Cl⁻ ligands of eight SnII ions (K-Cl: 3.155(5) Å).

According to bond valence sum calculations, all tungsten centers in 1 are in the oxidation state +VI and all oxygen atoms of \{P8W48\} are unprotonated (see Table S2†). Thus, the partial reduction of WVI centers in the \{P8W48\} precursor due to the reaction with SnII might explain the relatively low yield of KLi-1, the final formula of which was determined from crystal structural data, BVS calculations and elemental analysis.

To the best of our knowledge 1 is the first example of a \{P8W48\}-type polyanion with a main group metal, as only transition metal and lanthanide-functionalized \{P8W48\} derivatives have been reported to date. The main difference in SnII (vs. transition metal/lanthanide) complexation with \{P8W48\} is the relatively small coordination number (3) of SnII. This feature, however, limits the long-term solution stability of 1 (vide infra).

On the other hand, it leaves rather a significant space inside the \{Sn8P8W48\} macrocycles that can potentially be used to incorporate other ligands/metals.

In the solid-state structure of KLi-1 the polyanions 1 are interlinked via K⁺ countercations into a 3D framework with pseudolayers of 1 packed in an ABABAB⋯ pattern (Fig. S1 and S2†) along the crystallographic c axis. A network of channels along the a and b axes with 5 × 9 Å diameter are filled by crystal water molecules.

FT-IR spectrum

The FT-IR spectrum of KLi-1 (Fig. S3†) exhibits a set of bands in the range of 1135–400 cm⁻¹ typical of the \{P8W48\} framework. Thus, the positions of the bands characteristic of vibrations of P-O bonds in KLi-1 (1134, 1084 and 1022 cm⁻¹) are almost the same as those attributed to P-O vibrations of a tin-free K/Li salt, KLi-P₈W₄₈ (1138, 1083 and 1017 cm⁻¹), despite a small shoulder at 1120 cm⁻¹ for KLi-1. The intense band at 926 cm⁻¹ belongs to the stretching vibrations of the terminal W=O bonds. The main differences between KLi-1 and KLi-P₈W₄₈ in the 850–400 cm⁻¹ range concern W-O-W, W-O-P and W-O-Sn vibrations (716, 569, 530, 465 and 401 cm⁻¹ for KLi-1 and 807, 686, 573, 527 and 472 cm⁻¹ for KLi-P₈W₄₈) and, especially in the 850–550 cm⁻¹ region, reflect the SnII coordination to \{P8W48\}.

Characterization in aqueous solution

KLi-1 is soluble in water, and its solubility is significantly enhanced in the presence of Li⁺ ions. The addition of K⁺ salts to solutions of KLi-1 leads to immediate precipitation of the complex. The stability of the polyanions 1 in various Li⁺-based media has been investigated by 3¹P NMR and UV-Vis spectroscopy.

3¹P NMR spectroscopy

The room temperature liquid-state 3¹P NMR spectrum of 1 in a 2 M Li₂SO₄/H₂SO₄ buffer with pH 3.0 (Fig. 2) recorded within 1 h exhibits a single signal at −8.0 ppm which is in full agreement with the D₄h symmetry of 1 in the crystal lattice of KLi-1. It corresponds rather well to the signal at −7.6 ppm observed in the 3¹P MAS NMR solid-state spectrum of KLi-1 recorded at 67 kHz rotation frequency (Fig. S6†). Furthermore, it documents the single phase character of the material. The symmetric line shape of the 3¹P NMR spectrum measured without sample spinning indicates the absence of a significant chemical shift anisotropy confirming the tetrahedral coordination of the phosphorus atoms. The small difference in the chemical shift can be attributed to the heating of the sample during its fast rotation in the solid-state measurements. This also can be compared with a singlet at −6.5 ppm characteristic of non-coordinated KLi-P₈W₄₈ measured in the same medium (Fig. S7†). This result indicates short-term stability of the title compound in 2 M Li₂SO₄/H₂SO₄ buffer (pH 3.0). At the same time, after several hours other signals start to appear in the spectrum evident of slow decomposition of 1 in aqueous solution via the gradual release of SnII ions. Thus, the spectrum of the same solution measured for 1 day (Fig. S8†) shows a set of additional, weaker signals at −8.1 ppm (13.6% of the total intensity of all the signals), −8.3 ppm (6.1%), −8.4 ppm (2.7%), −8.7 ppm (2.3%), −8.8 ppm (1.4%) and −10.7 ppm (6.4%) along with the original one at −8.0 ppm (67.5%). The decomposition of the polyanion in 4 M LiCl seems to be even faster, already after one hour the spectrum of KLi-1 redissolved in this medium exhibits a set of badly resolved signals in the range of −6.3 to −15 ppm.
−7.5 ppm (85%) and two singlets at −8.0 (8.8%) and −10.7 ppm (6.2%). The $^{31}$P NMR spectrum of I in this medium (Fig. S9†) does not change further significantly within 24 h. The signals at −8.1 and −10.7 ppm in the spectra measured in both 2 M Li$_2$SO$_4$ (pH 3.0) and 4 M LiCl after 24 h suggest the existence of a rather stable decomposition intermediate(s) of the {Sn$_8$P$_8$W$_{48}$} complex, most likely of composition {Sn$_8$P$_8$W$_{48}$} with $x < 8$, which form via the release of one or more Sn$^{IV}$ centers from {Sn$_8$P$_8$W$_{48}$}.

**UV-Vis spectroscopy.** The solutions of KLi-I were further examined using absorption spectroscopy to check for the solution stability of the {Sn$_8$P$_8$W$_{48}$} complex at small concentrations (ca. 10$^{-4}$ M). The UV-Vis spectrum of KLi-I redissolved in 2 M Li$_2$SO$_4$/H$_2$SO$_4$ buffer (pH 3.0) exhibits two strong absorption maxima at 216 nm ($\epsilon = 97 800$ M$^{-1}$ cm$^{-1}$) and 275 nm ($\epsilon = 97 800$ M$^{-1}$ cm$^{-1}$) and at 385 nm ($\epsilon = 9800$ M$^{-1}$ cm$^{-1}$), responsible for the orange color of the compound (Fig. S10†).

Time-dependent measurements on solutions of KLi-I in 2 M Li$_2$SO$_4$/H$_2$SO$_4$ buffer (pH 3.0) ($c = 1.0 \times 10^{-4}$ M) show a gradual decrease in the intensity of the maximum at 385 nm starting after 1.5−2 h (Fig. S11 and S12†), which supports the conclusions on slow solution decomposition of the polyanions based on the $^{31}$P NMR spectroscopy data. The spectra in some other media show similar characteristics (see the Experimental section and Fig. S13 and S14†).

**Electrochemical studies.** Compound I was studied by cyclic voltammetry in three different media: (1) 1 M LiCl + HCl (pH = 2.0); (2) 0.5 M Li$_2$SO$_4$ + H$_2$SO$_4$ (pH 2.0) and (3) 2 M LiCl (unbuffered). As expected, the medium in which the observed waves are best defined is the one exhibiting the highest buffering power, 0.5 M Li$_2$SO$_4$/H$_2$SO$_4$ (pH 2.0) (Fig. S13†). In fact, previous studies showed that the parent compound of I, the polyanion {P$_8$W$_{48}$}, reacts as an effective proton sponge.16 The presence of 8 Sn$^{II}$ centers does not seem to modify nor attenuate this behavior. A comparison of the CVs of I and {P$_8$W$_{48}$} taken as reference, recorded in 0.5 M Li$_2$SO$_4$ + H$_2$SO$_4$ (pH 2.0) (Fig. 3), reveals three main differences: (I) the redox waves attributed to the W$^{VI}$ centers are better separated on the CV of I, having two clearly defined reduction steps. (II) The reduction of the W$^{VI}$ centers takes place at far less negative potentials compared to those of {P$_8$W$_{48}$} ($\Delta V = 160$ mV). (III) There is a new redox wave assigned to the reduction of the W$^{VI}$ centers. This wave, with a shape characteristic of adsorption/desorption processes taking place on the surface of the working electrode, is assigned to the reduction of the Sn$^{II}$ centers to Sn$^{0}$ and to the formation of a metallic tin film on the surface of the GC electrode. Upon scan reversal, there is the re-dissolution wave of tin concomitant with its electrochemical re-oxidation: Sn$^{0}$ = Sn$^{II}$ + 2e$^-$. When lower scan rates are employed and the potential is restricted to a range excluding this third wave ($E > −0.58$ V vs. SCE), it is clear that just the W$^{VI}$ centers are reduced, and the Sn$^{II}$ centers are not affected (Fig. S16†).

In order to prove unambiguously that the potential scan restricted to a range not going below −0.58 V vs. SCE concerns just the W centers, we carried out a study of the dependence of the reduction and oxidation peak currents, $I_{pc}$ and $I_{pa}$, on the scan rate. It revealed that $I_{pc}$ depends on the square root of the scan rate, despite the fact that a relatively narrow set of scan rates was used (10 to 50 mV s$^{-1}$), this confirms that the mass transport phenomena coupled to the electron transfer are diffusion controlled, excluding the possible involvement of the Sn centers (Fig. S17†).

**Electrochemical quartz crystal microbalance (EQCM) characterization.** In order to confirm undoubtedly that there is a metal tin film forming on the surface of the working electrode during the cyclic voltammetry experiment when the potential range goes beyond the W centers’ redox waves, meaning that a wave assignable to the Sn$^{II}$/Sn$^{0}$ redox couple is present, a quartz crystal microbalance was coupled to the electrochemistry setup. A potential scan was carried out at a low rate (2 mV s$^{-1}$) in order to favor the deposit of the Sn$^{0}$ film. In addition, when two consecutive scans are recorded, the GC electrode surface is perfectly regenerated upon the reverse scan. The quartz crystal vibration frequency variation indicates that the Sn$^{0}$ film starts depositing at a potential of −0.6 V vs. SCE and continues even after the potential scan is reversed. This potential of −0.6 V vs. SCE seems to be the threshold value both for the onset of the Sn$^{II}$ reduction and for the onset of the re-oxidation of Sn$^{0}$ (Fig. 4). It is possible to estimate the amount of accumulated tin after each cycle, but we did not find it crucial in the context of the present study.

**Experimental section**

**General methods and materials**

The reagents were used as purchased without further purification. K$_{28}$Li$_5$[H$_2$P$_8$W$_{48}$O$_{184}$]·92H$_2$O (KLi-P$_8$W$_{48}$) was obtained according to the reported procedure$^{15}$ and its identity and purity were confirmed by IR and $^{31}$P NMR spectroscopy.
Elemental analysis results (ICP-OES) were obtained from Central Institute for Engineering, Electronics and Analytics (ZEA-3), Forschungszentrum Jülich GmbH (D-52425 Jülich, Germany). TGA/DTA measurements were carried out with a Mettler Toledo TGA/SDTA 851 in dry N2 (60 ml min\(^{-1}\)) at a heating rate of 5 K min\(^{-1}\). Vibrational spectra were recorded on a Bruker Vertex 70 FT-IR spectrometer coupled with a RAM II FT-IR-Raman module (1064 nm Nd:YAG laser) on KBr disks for the FT-IR and the solid material for the Raman measurements. UV-Vis spectra were recorded using 10 mm quartz cuvettes on a SuperNova (Agilent Technologies) diode array detector. Single-crystal X-ray diffraction data for KLi-1 were collected on a SuperNova (Agilent Technologies) diffractometer with Mo Kα radiation (\(\lambda = 0.71073\) Å) at 120 K. A crystal was mounted on a Hampton cryoloop with Paratone-N oil to prevent water loss. Absorption corrections were applied numerically based on a multifaceted crystal model using CrysAlis software.\(^{27}\) The SHELXTL software package\(^{18}\) was used to solve and refine the structure. The structure was solved by the direct methods and refined by the full-matrix least-squares method against \(F^2\) with anisotropic thermal parameters for all POM skeleton atoms (Sn, Cl, P, W, O) and potassium countercations and in isotropic approximation for the O atoms of co-crystallized solvent molecules. The Li\(^+\) countercations and hydrogen atoms of the crystal water molecules were not located. The relative site occupancy factors for the disordered potassium countercations and solvent oxygens were first refined in an isotropic approximation with \(U_{eq} = 0.05\) and then fixed at the same value.

obtained values and refined without the thermal parameter restrictions.

The number of crystal water molecules found by XRD was smaller than that determined by elemental analysis and TGA (41 vs. 50 and 102, respectively) reflecting the high degree of solvent disorder in the solid-state structure of KLi-1. This is also consistent with large solvent-accessible volume remaining in the structure. On the other hand, the sample used for further studies were performed on the isolated well-dried bulk material of KLi-1. Additional crystallographic data are summarized in Table 1. Further details on the crystal structure investigation may be obtained from Fachinformationszentrum Karlsruhe, 76344 Eggenstein-Leopoldshafen, Germany [fax (+49) 7247-808-666; e-mail crysdata@fiz-karlsruhe.de], upon quoting the depository number CSD 429908.

Electrochemical experiments

Cyclic voltammograms of 1 were recorded in comparison with the heterometal-free [P₅W₄₈] salt KLi-P₅W₄₈ at room temperature in three different media: (1) on a 0.55 mM solution of KLi-1 in 1 M LiCl/HCl buffer (pH 2.0), (2) 0.57 mM solution of KLi-1 in 0.5 M Li₂SO₄/H₂SO₄ buffer (pH 2.0) and (3) 0.52 mM non-buffered KLi-1 solution in 2 M LiCl. The corresponding concentrations of KLi-P₅W₄₈ were 0.51 mM, 0.56 mM and 0.53 mM, respectively. Electrochemical data were obtained using an EG&G 273A potentiostat controlled by M270 software. A conventional one-compartment three-electrode electrochemical cell included a glassy carbon working electrode (GC, Mersen, France) with a diameter of 3 mm, a platinum gauze counter electrode with a large surface area and a saturated calomel reference electrode. The source, mounting, and polishing of the glassy carbon electrode has been previously described.19 The reference and counter electrodes were separated from the studied solutions via fritted compartments filled with the same electrolyte. Prior to the experiments the solutions were thoroughly deaerated with pure argon for at least 30 min and then kept under a positive argon pressure during the measurements. The midpoint redox potentials were determined from the average values of the anodic and cathodic peak potentials and are reported vs. the saturated calomel reference electrode (SCE).

The electrochemical quartz crystal microbalance (EQCM) measurements were carried out using a QCA 922 (Seiko/EG&G) system with 9 MHz AT-cut crystals. New crystals equipped with carbon electrodes possessing a true surface area of 0.3 cm² were provided by Seiko. Frequency variations were recorded and used for discussion in this work.

Conclusions

In summary, we have prepared the first complex of macrocyclic phosphotungstate with the main group metal ions, [K₄.5(ClSn)₈P₅W₄₈O₁₈₄]¹⁺ (1), which also represents a rather rare example of SnII-containing POMs. In 1 the SnII centers occupy the eight vacant sites of the polyanion resulting in the POT with D₅h symmetry. Polyanions 1 have been isolated in the solid state as the hydrated mixed potassium/lithium salt KLi-1 and characterized by single-crystal X-ray diffraction, FT-IR/Raman and ³¹P MAS NMR spectroscopy as well as by elemental and thermogravimetric analyses. Solution studies by ³¹P NMR, UV-Vis and electrochemistry showed that the complex is stable in aqueous medium for several hours and then slowly decomposes, releasing SnII. In contrast with transition metal and lanthanide-functionalyzed POMs, the SnII ions in 1 display a small coordination number of 3 and coordinate only one terminal Cl⁻ ligand each, thus retaining a relatively large void in the inner cavity of the macrocyclic complex. Currently we are investigating the possibility of further functionalization of [Sn₅P₅W₄₈] via incorporation of various heterometals in this inner core volume.
