# Oxygen-tolerant proton reduction catalysis: much O<sub>2</sub> about nothing?†

David W. Wakerley and Erwin Reisner\*

Proton reduction catalysts are an integral component of artificial photosynthetic systems for the production of H<sub>2</sub>. This perspective covers such catalysts with respect to their tolerance towards the potential catalyst inhibitor O<sub>2</sub>. O<sub>2</sub> is abundant in our atmosphere and generated as a by-product during the water splitting process, therefore maintaining proton reduction activity in the presence of O<sub>2</sub> is important for the widespread production of H<sub>2</sub>. This perspective article summarises viable strategies for avoiding the adverse effects of aerobic environments to encourage their adoption and improvement in future research. H<sub>2</sub>-evolving enzymatic systems, molecular synthetic catalysts and catalytic surfaces are discussed with respect to their interaction with O<sub>2</sub> and analytical techniques through which O<sub>2</sub>-tolerant catalysts can be studied are described.

## Broader context

The generation of hydrogen from water is a potential approach to develop a clean and renewable fuel. This process is carried out by proton reduction catalysts and currently research is focussed on the development of efficient and robust catalytic species. Application of the water-splitting process will be carried out on a large scale, not restricted to the laboratory, and as such it is necessary to consider how O<sub>2</sub> in our atmosphere or produced as a side product from water splitting would interact with such an arrangement. O<sub>2</sub> is an inhibitor of a number of catalytic processes and therefore designing strategies to avoid O<sub>2</sub> inhibition is crucial in the production of viable proton reduction systems.

## 1. Introduction

The large scale production of H<sub>2</sub> through artificial photosynthesis stands as an aspiring goal of contemporary science.<sup>1–3</sup> Chemical-energy storage through water splitting generates both H<sub>2</sub> and O<sub>2</sub> and relies on efficient reduction and oxidation catalysts, respectively [reaction (1)].

Research into viable catalysts is consequently gathering significant interest,<sup>4</sup> but there remain several limitations that must be addressed before such systems can be implemented on a commercial scale. For example, avoiding non-aqueous solutions, increasing long-term stability and sustaining high catalytic efficiency are all goals for a benchmark catalyst and progress in these areas has proceeded at an appreciable rate.

One issue that remains relatively underexplored is the impact of O<sub>2</sub> on synthetic proton-reducing systems. Less than a decade ago it seemed common sense that synthetic molecular H<sub>2</sub>-evolving catalysts would operate poorly under air due to the propensity of O<sub>2</sub> to irreversibly damage a catalytic structure during turnover. As a result, research was carried out under inert atmospheres of N<sub>2</sub> or Ar. Given that the end goal for a proton reduction catalyst would be its widespread use in a H<sub>2</sub>-fuelled economy, any observable O<sub>2</sub>-sensitivity would seriously impair its practicality. Adding to this, stringent anaerobic conditions are costly to maintain on an industrial scale. Developing catalysts that could operate under O<sub>2</sub> consequently stood as a major challenge for H<sub>2</sub> production research,<sup>5,6</sup> yet recent publications have demonstrated that avoiding the inhibiting effects of O<sub>2</sub> may be more manageable than first imagined and O<sub>2</sub>-tolerant proton reduction is now a fast-developing field.

Exposure of a proton reduction catalyst to O<sub>2</sub> in a water splitting system, particularly over prolonged periods of time, is almost unavoidable. Fig. 1a shows a standard electrolyser/photoelectrochemical (PEC) cell, which contains an O<sub>2</sub> evolving anode and a H<sub>2</sub> producing cathode separated by a proton exchange membrane to prevent crossover of the evolved gaseous products.<sup>7</sup> Interaction between O<sub>2</sub> and the proton reducing

cathode can still occur through O<sub>2</sub> leakage from the atmosphere into the electrochemical cell or from the anodic chamber after membrane degradation.<sup>8,9</sup> Another configuration is the ‘artificial leaf’,<sup>10,11</sup> a simplification of which can be seen in Fig. 1b. The cathode and anode are attached on opposing sides of a photovoltaic layer that drives catalysis and some exposure of the proton reduction catalyst to O<sub>2</sub> is inherent in the system’s design. Photocatalytic water-splitting particles are also a promising route to full water splitting, see Fig. 1c.<sup>12,13</sup> H<sub>2</sub> and O<sub>2</sub> are produced on the same or a neighbouring light-absorbing particle, which is often loaded with a catalyst to enhance catalysis. The close proximity of O<sub>2</sub> and H<sub>2</sub> evolution sites makes interaction between catalyst and O<sub>2</sub> inevitable without additional protection of the catalyst.

Contemporary research has started to cover the concept of O<sub>2</sub>-tolerant H<sub>2</sub> generation to realise systems in which the presence of O<sub>2</sub> is inconsequential. This field is still in its infancy, nonetheless the reported O<sub>2</sub>-tolerant systems present innovative routes to efficient, aerobic proton reduction. Broadly speaking the current examples fall into one of three areas of catalyst: proton reducing enzymes (hydrogenases),<sup>14</sup> molecular complexes<sup>5</sup> and catalytic surfaces.<sup>15,16</sup>

In this perspective, each of these examples will be discussed to encourage a holistic development of O<sub>2</sub>-tolerant catalyst systems. A discussion of the electrochemical/spectroscopic study of O<sub>2</sub>-tolerance is also provided to highlight key techniques that will be vital for fully understanding the effects of O<sub>2</sub> on a proton reduction system.

## 2. Oxygen in a proton reducing system

Proton reduction is a pH dependent redox process that has a formal redox potential,  $E^{0'}$ , of 0 – (pH × 59) mV vs. the normal hydrogen electrode (NHE) (25 °C). Applied potentials more negative than  $E^{0'}$  are needed to drive H<sub>2</sub> evolution and under

aerobic conditions it is necessary to consider the effect such potentials have on O<sub>2</sub>. In a pH 7 solution there are a number of potential O<sub>2</sub> reduction reactions that could occur, many of which form reactive oxygen species (ROS):<sup>17</sup>

Water formation:

ROS formation:

ROS reduction

Proton reduction:

Potentials stated vs. NHE

Direct O<sub>2</sub> reduction to water through reaction (2) forms the most thermodynamically stable product, but the process is kinetically slow due to the high dissociation energy of the dioxygen bond,<sup>18</sup> which has a considerable thermodynamic barrier of 498 kJ mol<sup>-1</sup>. The reduction also requires 4e<sup>-</sup> and 4H<sup>+</sup> and therefore, with the exception of a few highly active catalytic sites, it is much more likely that incomplete O<sub>2</sub> reduction occurs to form H<sub>2</sub>O<sub>2</sub>, O<sub>2</sub><sup>•-</sup> or •OH if sufficiently reducing conditions are available [reactions (3) to (5)]. These species can subsequently be reduced to water in a multi-step reaction sequence [reactions (6) to (8)].

Each of the O<sub>2</sub>-reduction reactions (2) to (8) occurs at a less negative potential than the proton reduction reaction (9), which implies that any system capable of reducing protons will have sufficient driving force for O<sub>2</sub> reduction to either generate water or ROS. It should be noted that photochemical systems may also generate reactive singlet O<sub>2</sub> (<sup>1</sup>O<sub>2</sub>) through triplet-triplet annihilation. The interaction of a H<sub>2</sub> evolving catalyst with O<sub>2</sub> has two potential outcomes: O<sub>2</sub>-tolerant proton reduction or inhibited catalysis due to O<sub>2</sub>-sensitivity (Fig. 2).

### Oxygen-sensitive catalyst

O<sub>2</sub>-sensitive proton reduction catalysts undergo a critical drop in H<sub>2</sub> production activity in the presence of O<sub>2</sub>. In this case the catalyst is susceptible to deactivation by reaction with O<sub>2</sub> or

Fig. 2 Two routes through which O<sub>2</sub> can affect catalytic proton reduction.

with the ROS produced in reactions (3)–(5) or (8). The reducing sites at which  $O_2$  or ROS attack are typically essential to proton reduction activity and therefore the catalyst is irreversibly inhibited.

$O_2$ -sensitive catalysts require a defensive approach to overcome irreversible  $O_2$  inhibition (see below). This involves protecting a catalyst from exposure to  $O_2$ /ROS in order to generate a locally anaerobic environment.

### Oxygen-tolerant catalyst

$O_2$ -tolerance is a term used to describe a catalyst that maintains a degree of activity in the presence of  $O_2$ . In this case the catalyst is able to reduce the incoming  $O_2$  or ROS without being irreversibly damaged. Proton reduction is therefore in competition with  $O_2$  reduction and  $H_2$  is often produced at a decreased rate and efficiency under aerobic conditions.

The reduction of  $O_2$  by  $O_2$ -tolerant catalysts can be seen as an offensive approach to prevent  $O_2$ -inhibition. The catalyst is able to remove  $O_2$  as a threat and allows  $H_2$  evolution to continue. Designing a proton reduction catalyst capable of reducing  $O_2$  and ROS to harmless by-products is an elegant strategy to realise aerobic proton reduction.  $O_2$ -tolerance can be enhanced further through design of a catalyst that has favourable kinetics for proton reduction over  $O_2$  reduction.

## 3. Analytical techniques to study oxygen tolerance

Studying the  $O_2$  tolerance of a proton reducing species is a relatively new line of research and as such, routine analytical techniques are not commonplace in most laboratories. Currently, electrochemistry offers the simplest and most effective approach. Analysis of currents stemming from a catalyst and quantification of the  $H_2$  produced can be used to calculate turnover frequencies (TOFs),<sup>19</sup> turnover numbers (TONs) and determine redox processes under  $O_2$ .<sup>20</sup> These techniques can be applied across all types of  $H_2$ -evolving catalysts.

Cyclic voltammetry (CV) offers a fast method to study redox changes and catalytic currents. CV analysis starts from a catalytically-inert potential and scans to a more negative potential at which clear proton reduction currents are observable. The onset of proton reduction and size of the reduction wave, along with Tafel slope analysis, provide a measure of a catalyst's activity. The first step in the study of  $O_2$  tolerance is to establish whether this activity changes under aerobic conditions. If a catalyst is  $O_2$  sensitive, a CV in air will result in a significant drop in proton reduction current, whereas little change in the proton reduction wave indicates  $O_2$ -tolerant catalysis. An  $O_2$ -tolerant catalyst may also display an  $O_2$  reduction wave, demonstrating simultaneous proton/ $O_2$  reduction.  $O_2$  tolerance is visible on a Pt electrode, where an  $O_2$  reduction wave (onset +0.5 V vs. NHE) can be observed under an  $O_2$  atmosphere, whilst the proton reduction wave (onset around -0.4 V) is maintained (Fig. 3). CV only gives an indication of  $O_2$ -tolerance on a short time-scale, and analysis must therefore be supplemented with other techniques.

Fig. 3 Cyclic voltammograms on a Pt disk electrode in phosphate buffer (pH 7, 0.1 M) under aerobic and anaerobic conditions under  $N_2$  at a scan rate of  $50 \text{ mV s}^{-1}$  at room temperature.<sup>21</sup> The anodic wave can be attributed to the oxidation of  $H_2$  generated during the cathodic scan.

Controlled potential electrolysis (CPE) is another vital tool in the study of proton reduction catalysis. In this process a constant potential is applied to a catalyst, allowing measurable quantities of  $H_2$  to build up that can be quantified through techniques such as gas chromatography. Confirming that  $H_2$  has been produced under aerobic conditions is of paramount importance, as otherwise it is not clear if an observed current stems from  $H_2$  evolution or  $O_2$ /ROS reduction. Quantification of  $H_2$  also allows the Faradaic efficiency (FE) to be calculated. FE is a measure of the electrons used vs. the  $H_2$  produced and would be 100% if all electrons were consumed for proton reduction. Quantification of the  $H_2$  produced and FE from CPE under aerobic and anaerobic atmospheres gives a clear indication of a catalyst's  $O_2$  tolerance and selectivity for proton reduction over  $O_2$  reduction. CPE is also necessary to establish long-term catalytic stability under  $O_2$ , as inhibition may occur over prolonged  $O_2$ /ROS exposure. Such experiments may be further extended to include the effect of varying levels of  $O_2$  on catalysis.

Interaction between photocatalysts and  $O_2$  may also be studied using surface photovoltage spectroscopy. This technique monitors the contact potential difference as a function of photon energy in order to determine the surface states and energy necessary for  $O_2$  reduction on a given substrate.<sup>22</sup>

At present, analysis of  $O_2$ -tolerance is confined to measuring the  $H_2$  produced by a catalyst with and without  $O_2$ , however this should be coupled with analysis of the formed ROS to gain a complete appreciation of the catalyst's aerobic activity. Rotating ring-disk electrochemistry is one of the most common methods of ROS detection, which can distinguish the production of  $H_2O_2$  vs.  $H_2O$ . This technique requires a disk electrode, consisting of the catalyst to be studied, encircled by an electrode ring, which is typically Pt. When this electrode is rotated there is laminar flow of solution from the central disk to the outer ring electrode.<sup>20</sup> By holding the ring at oxidizing potentials with a bipotentiostat, it is possible to detect products from  $O_2$  and  $H^+$  reduction through their unique redox potentials. This technique can be used to monitor the production of  $H_2O_2$  or  $H_2$ ,<sup>23</sup> which can determine the degree of selectivity and  $O_2$ -tolerance of a given proton reduction catalyst.<sup>24</sup>

A range of electrochemical sensors can similarly be implemented to detect the formation of ROS. Detection of  $O_2^{\bullet-}$  has been achieved by a number of protein-based electrodes, such as those loaded with superoxide dismutase<sup>25–27</sup> or cytochrome *c*<sup>28,29</sup> and more recently, protein-free detectors have been utilised.<sup>30–32</sup> Similarly  $H_2O_2$  can be detected through attachment of horseradish peroxidase,<sup>33</sup> cytochrome *c*<sup>34</sup> or CuS<sup>35</sup> to an electrode. This subject has recently been reviewed.<sup>36</sup>

ROS detection can also be achieved through the measurement of a unique spectroscopic signal, such as the UV peak of  $H_2O_2$ <sup>37</sup> and mass-spectrometry allows the quantification of  $^{18}O_2$  reduction to  $H_2^{18}O$ . Alternatively, spectroscopic probes can be used, which can specifically determine nM concentrations of a given ROS.<sup>38</sup> Spectroscopic probing of the catalyst during proton reduction is equally important in order to visualise the structural and electronic changes that lead to  $O_2$ -sensitivity and tolerance. Through such analysis a complete appreciation for ROS/ $H_2$  formed at a given applied potential vs. current expended can be realised, allowing conclusions concerning the interaction of the catalyst with  $O_2$  to be drawn.

## 4. Oxygen-tolerant hydrogenases

Hydrogenases are nature's  $H_2$ -cycling catalysts and display a high 'per active site' activity with TOFs up to  $10^4\ s^{-1}$ , rivalling that of Pt.<sup>39,40</sup> These enzymes consist of well-suited structures to undertake proton reduction/ $H_2$  oxidation and as such have received much attention.<sup>14</sup> [NiFe] and [FeFe] hydrogenases, categorised according to their active site composition, are the two classes of hydrogenases capable of proton reduction to  $H_2$ . In each hydrogenase the active metal ions are ligated by  $CN^-$ , CO and cysteine ligands and are typically connected to the protein exterior *via* iron–sulphur clusters. The disadvantages to the use of hydrogenases include difficult and costly purification, fragility, a large catalyst footprint (high 'volume per active site' ratio) and an infamous sensitivity to small quantities of  $O_2$ .

Hydrogenase interaction with  $O_2$  is a considerably well-established area of research and may be instrumental in engineering  $O_2$ -tolerant synthetic systems.<sup>41</sup> In-depth electrochemical and spectroscopic studies have illustrated the route to  $O_2$  inhibition across a range of hydrogenases and this work has been reviewed a number of times.<sup>14,42</sup> As such this perspective will only briefly summarise the interaction between hydrogenases and  $O_2$  and instead focus on emerging strategies to shield the enzyme from aerobic atmospheres.

Both classes of hydrogenase consist of a range of subclasses and the  $O_2$  susceptibility of each depends to some extent on the environment in which the enzyme functions biologically. Generally, both the [NiFe] and [FeFe] hydrogenases are inhibited by  $O_2$  due to their interaction with ROS. Upon exposure of a [FeFe] hydrogenase to air, the active site, known as the H-cluster, is believed to form a ROS, which oxidises its proximal [4Fe–4S] cluster and prevents electron transfer through the enzyme to the active site.<sup>44</sup> [NiFe] hydrogenases deactivate through the reduction of  $O_2$  to form an oxidised and paramagnetic 'unready' Ni-A state of

Fig. 4 (a) Schematic representation of the formation and recovery of the oxidised Ni-A and Ni-B states in the [NiFe] hydrogenase active site (adapted from ref. 43). (b) Active site of the [NiFeSe] hydrogenase and two reported oxidised structures from *Desulfomicrobium baculatum* (Ox4B state) and *Desulfovibrio vulgaris* (conformer I).

the active site that is slow to reactivate<sup>45</sup> (see Fig. 4a). The exact form of this state is debated, but crystallographic studies have suggested that a hydroperoxo ligand is ligated to the Ni ion as a result of incomplete  $O_2$  reduction.<sup>46</sup>

The concept of  $O_2$ -tolerant  $H_2$  oxidation has become an exciting branch of research, in particular for the membrane-bound [NiFe] hydrogenase from *Ralstonia eutropha*, which can oxidise  $H_2$  under atmospheric levels of  $O_2$ .<sup>47–49</sup>  $O_2$ -tolerant hydrogenases are more likely to form a paramagnetic Ni-B (or 'ready') state upon exposure to  $O_2$ , as a result of more complete  $O_2$  reduction to form a bridging hydroxo ligand.<sup>46</sup> The route to their tolerance is believed to originate from six cysteine residues surrounding the unique proximal [4Fe–3S] cluster next to the enzyme's active site.<sup>50</sup> The cysteines facilitate structural changes that allow the cluster to transfer two electrons within a small potential range.<sup>51,52</sup> When  $O_2$  enters the active site, one electron from the reduced Ni and two from the proximal [4Fe–3S] cluster allow the hydrogenase to consistently form the Ni-B state (Fig. 4a), which very quickly reactivates ( $t < 1\ min$ ). Recent evidence has suggested that conversion from Ni-A to Ni-B may occur through the oxygenation of one of the bridging S-atoms.<sup>53</sup> Despite promising  $O_2$ -tolerance, this exceptional type of [NiFe] hydrogenase is biased towards  $H_2$  oxidation over proton reduction and is inhibited by  $H_2$ .<sup>42</sup>

The [NiFeSe] hydrogenase is a subclass of the [NiFe] hydrogenase that is highly active for proton reduction in the presence

of  $\text{H}_2$  and illustrates a promising degree of tolerance to  $\text{O}_2$ .<sup>14</sup> [NiFeSe] hydrogenases contain a ligated selenocysteine moiety in place of one of the terminal cysteines of the conventional [NiFe] enzyme (Fig. 4).  $\text{O}_2$  exposure of the enzyme does not form substantial quantities of Ni-A/Ni-B states as a paramagnetic  $\text{Ni}^{\text{III}}$  is not observed.<sup>54</sup> The major products from oxidation of two [NiFeSe] hydrogenases are presented in Fig. 4b. The active site from *Desulfomicrobium baculatum* when crystallised aerobically contains an oxidised selenocysteine moiety (referred to as Ox4B)<sup>54</sup> and the *Desulfovibrio vulgaris* species, when purified and crystallised aerobically, contains an oxidised Se and doubly-oxidised S (referred to as conformer I).<sup>55,56</sup> The chemical role of selenocysteine in protecting the hydrogenase from oxidative damage is currently under investigation,<sup>57</sup> but it has been shown that the [NiFeSe] hydrogenase is able to reactivate faster under anaerobic conditions after  $\text{O}_2$ -exposure in comparison to the  $\text{O}_2$ -sensitive [NiFe] species.<sup>58</sup> The  $\text{O}_2$  tolerance may be a result of the easier redox chemistry of Se compared to S.<sup>59</sup>

Due to the extreme  $\text{O}_2$  sensitivity of many hydrogenases, engineering the enzymes to reduce protons and  $\text{O}_2$  simultaneously is a significant challenge,<sup>60,61</sup> and currently more practicable approaches to aerobic  $\text{H}_2$ -evolution involve shielding the enzyme from exposure to  $\text{O}_2$ . This involves a 'retrofitted'  $\text{O}_2$ -defending shield that reduces  $\text{O}_2$  before it can have adverse effects on enzyme activity. To date, 'shields' have been predominantly based on photochemical systems that remove  $\text{O}_2$  from a system during irradiation.

In 2009 we reported that *Desulfomicrobium baculatum* [NiFeSe] hydrogenase attached to a Ru-sensitised  $\text{TiO}_2$  nanoparticle was able to produce  $\text{H}_2$  photocatalytically in a  $\text{N}_2$  purged vial outside a glovebox.<sup>64</sup> Although this sacrificial photosystem sustains  $\text{H}_2$  generation under traces of  $\text{O}_2$ , it cannot maintain photo- $\text{H}_2$  production

activity under atmospheric  $\text{O}_2$  levels due to the lack of efficient  $\text{O}_2$  shielding and presumably enzyme-damaging ROS formation on irradiated  $\text{TiO}_2$  in the presence of  $\text{O}_2$  (see Section 5).

Peters and coworkers showed in 2012 that a [NiFe] hydrogenase from *Thiocapsa roseopersicina* covalently linked to a Ru dye was able to photocatalytically reduce protons under aerobic conditions in the presence of the soluble redox mediator methyl viologen (MV) and a sacrificial electron donor.<sup>65</sup> Under an aerobic atmosphere and an initial lag period, where presumably dissolved  $\text{O}_2$  was photo-reduced, this system generated  $\text{H}_2$  at 11% of the initial rate observed under pseudo-inert conditions. An analogous system that used a Ru dye, which was not linked to the enzyme, showed no activity under air. It was therefore concluded that by attaching the Ru dye to the hydrogenase a local concentration of reduced MV was generated around the hydrogenase, which reduced  $\text{O}_2$  before it reached the enzyme and partially shielded it from inhibition.

Another example of  $\text{O}_2$ -shielding came in 2013,<sup>62</sup> when we reported photocatalytic  $\text{H}_2$  production with a *Desulfomicrobium baculatum* [NiFeSe] hydrogenase and the organic dye eosin Y in the presence of a sacrificial electron donor (Fig. 5a). The photo-activity of this mediator-free system was tested under increasing concentrations of  $\text{O}_2$  and it was able to maintain a notable degree of photocatalytic activity. Even under 21%  $\text{O}_2$ , 10% of the enzyme's activity (corresponding to a TOF of  $1.5 \text{ s}^{-1}$ ) was sustained relative to the anaerobic experiment, without the observation of a significant lag phase to start  $\text{H}_2$  production. Excited eosin Y promotes proton reduction, reduction of  $\text{O}_2$  and conversion of  $\text{O}_2$  to  $^1\text{O}_2$ .<sup>66</sup> The  $\text{O}_2$ -tolerance of the system may therefore stem from the photo-reduction of  $\text{O}_2$  and fast formation of  $^1\text{O}_2$  by the dye, which presumably reacts with eosin Y or the electron donor to create an anaerobic environment (Fig. 5a).

**Fig. 5** (a) Photo-excited eosin Y as a shield to protect a [NiFeSe] hydrogenase.<sup>62</sup> (b)  $\text{O}_2$ -shielding strategy based on a multi-component system consisting of a Ru dye, methyl viologen as soluble redox mediator and a hydrogenase in nanoporous glass. Reduced methyl viologen is generated upon photo-excitation of the dye and used to reduce the hydrogenase and quench  $\text{O}_2$  inside the pores to produce an anaerobic environment.<sup>63</sup> The sacrificial electron donor used to quench the dye omitted for clarity in (a) and (b).

The concept of shielding has been extended by Dewa and coworkers in 2014 through the implementation of porous enzyme-immobilising frameworks.<sup>63</sup> In this case, a nanoporous glass plate was soaked in a tris(bipyridine)ruthenium<sup>II</sup> dye, MV and a [NiFe] hydrogenase from *Desulfovibrio vulgaris*. The nanoporous framework consisted of 50 nm channels that directed diffusion of O<sub>2</sub> into the structure. The MV reduced O<sub>2</sub> in the channels as it entered the glass during irradiation, producing a shielded pathway that allowed protons to reach the hydrogenase but not O<sub>2</sub> (Fig. 5b). The glass framework thereby allowed sacrificial H<sub>2</sub> evolution to be powered photocatalytically through the Ru dye. The system was able to generate H<sub>2</sub> at photocatalytic rates as high as 7.9 s<sup>-1</sup> per enzyme, with a TON of 130 000 over 12 hours under aerobic atmospheres.

Shielding strategies have also been applied to H<sub>2</sub> oxidising systems. Redox active polymers containing viologen moieties are capable of simultaneously immobilising and protecting hydrogenases during H<sub>2</sub> oxidation,<sup>67,68</sup> and 3D porous carbon electrodes loaded with hydrogenase have sustained H<sub>2</sub> oxidation activity by favouring the effusion of H<sub>2</sub> over O<sub>2</sub>.<sup>69</sup> These approaches could also be employed for H<sub>2</sub> evolving systems.

Despite being complex and multifaceted, the interaction between hydrogenases and O<sub>2</sub> is generally thoroughly investigated. Yet there is currently enormous scope for the development of improved O<sub>2</sub> shielding systems and scaffolds to protect the enzyme and allow the use of more O<sub>2</sub>-sensitive hydrogenases in less stringent environments. Future work should remove redox mediators and sacrificial agents from these systems and focus on constructing O<sub>2</sub> shields on hydrogenase-modified electrodes to retroactively produce O<sub>2</sub>-tolerant hydrogenase systems.

## 5. Oxygen-tolerant molecular synthetic catalysts

Synthetic molecular catalysts are discrete transition metal complexes consisting of metal/ligand combinations designed to promote proton reduction.<sup>4,70</sup> Study of their activity is normally restricted to the homogeneous phase, containing the dissolved catalyst and an electron source, which is typically an electrode, a dye with a sacrificial electron donor or a strong chemical reducing agent. Recent examples have shown innovative rational design<sup>71–75</sup> and the field has been reviewed numerous times.<sup>5,76</sup> These catalysts do not typically exhibit TONs or TOFs comparable to hydrogenases and the most active solid-state catalysts, but offer a defined catalytic site that can be easily manipulated and used to establish functionality and mechanisms that are essential for efficient proton reduction activity.

Molecular catalysts are often inspired by the active site of hydrogenases and are frequently referred to as ‘artificial hydrogenases’ accordingly.<sup>77</sup> Due to the low tolerance of hydrogenases towards O<sub>2</sub>, for a long time molecular catalysts were assumed to be unusable under aerobic conditions,<sup>5</sup> however it is becoming increasingly apparent that molecular synthetic catalysts do not necessarily exhibit the debilitating O<sub>2</sub>-sensitivity of the enzymes they mimic.

Fig. 6 Currently known Co-based O<sub>2</sub>-tolerant molecular proton reduction catalysts. **1A**: water-soluble cobaloxime;<sup>78</sup> **1B**: fluorinated Co corrole;<sup>80</sup> **1C**: acetylated Co microperoxidase-11;<sup>81</sup> **1D/1E**: Co polypyridyl catalysts.<sup>82,83</sup>

Our group reported the first full study of O<sub>2</sub>-tolerant proton reduction with a synthetic molecular complex.<sup>78</sup> The study used a water-soluble [Et<sub>3</sub>NH][Co<sup>III</sup>Cl(dimethylglyoximate)<sub>2</sub>(pyridyl-4-hydrophosphonate)] catalyst (Fig. 6 shows fully protonated complex **1A**) and explored changes in activity under varying levels of O<sub>2</sub>. CVs of the catalyst were undertaken under N<sub>2</sub>, O<sub>2</sub> and CO (Fig. 7).<sup>79</sup> Catalytic currents were seen under N<sub>2</sub> and O<sub>2</sub> (Fig. 7a) but not CO, a known catalyst inhibitor (Fig. 7b). The large difference in proton reduction current between the CO-inhibited CV and the aerobic CV illustrates the O<sub>2</sub>-tolerant activity of the complex. Evidence of O<sub>2</sub> reduction was also visible as the non-catalytic Co<sup>II</sup>/Co<sup>III</sup> oxidation wave from the cobaloxime was not seen under aerobic conditions and the size of the Co<sup>III</sup>/Co<sup>II</sup> wave increased, indicating competitive O<sub>2</sub> reduction by the cobaloxime in the Co<sup>II</sup> oxidation state (Fig. 7a).

Subsequent CPE of this complex under inert and aerobic conditions at  $E_{\text{appl}} = -0.7$  V vs. NHE (0.29 V overpotential) showed that substantial H<sub>2</sub> production activity remained in the presence of O<sub>2</sub>. After re-purging the aerobic catalyst solution with N<sub>2</sub> and repeating CPE, the cobaloxime regained 100% of its initial activity, suggesting the drop in activity under air was a result of competitive O<sub>2</sub> reduction by the cobaloxime and not O<sub>2</sub> sensitivity.

Photochemical experiments supported this result. Catalysis was driven photochemically using either a heterogeneous Ru-photosensitised TiO<sub>2</sub> nanoparticle system or a homogeneous dye, eosin Y, and the evolved H<sub>2</sub> was measured under increasing concentrations of O<sub>2</sub>. Under 21% O<sub>2</sub>, 71% of the original H<sub>2</sub> evolution activity was measured in the homogenous system and

Fig. 7 CVs of **1A** (1 mM) in 0.1 M triethanolamine/Na<sub>2</sub>SO<sub>4</sub> at pH 7 under atmospheres of (a) N<sub>2</sub> and air and (b) N<sub>2</sub> and CO. Scan rate was 100 mV s<sup>-1</sup> on a glassy carbon working electrode. Taken from ref. 79.

17% was maintained in the colloidal system, which illustrated the O<sub>2</sub> tolerance of the cobaloxime complex. Subsequent experiments with other cobaloxime variants have shown similar levels of O<sub>2</sub> tolerance.<sup>24,84</sup>

It should be noted that the degree of O<sub>2</sub> tolerance exhibited by **1A** varied depending on the electron source and as such the dye or electrode and the correspondingly applied potential to the catalyst must be considered when studying molecular systems under O<sub>2</sub>. Most commonly used electrodes are capable of reducing O<sub>2</sub> to some extent and any currents stemming from a homogeneous catalyst must be deconvoluted from this background electrode activity. CVs of glassy carbon in air show a wave at -0.5 V vs. NHE in pH 7 solution (Fig. 7a, background) and FEs of a catalyst will typically be significantly less than the expected 100% for the same reason.<sup>79</sup> The photosensitiser will also react with O<sub>2</sub> during catalysis, lowering the rate of electron transfer to the catalyst and producing ROS. Organic dyes, such as fluorescein, rose bengal and eosin Y are common photosensitisers due to their appealing lack of precious metal centre, however under O<sub>2</sub> they are a source of <sup>1</sup>O<sub>2</sub>,<sup>66</sup> which will rapidly react with catalyst ligands. Ruthenium polypyridine dyes are similarly quenched by O<sub>2</sub>.<sup>85</sup> These dyes can be coupled to TiO<sub>2</sub> to assist in charge separation, however the TiO<sub>2</sub> is capable of producing ROS in the form of O<sub>2</sub><sup>•-</sup> and OOH<sup>-</sup> during irradiation.<sup>86</sup> The low activity of the heterogeneous TiO<sub>2</sub>-based system that drove photocatalysis of **1A** could be a result of O<sub>2</sub><sup>•-</sup> formation with concomitant desorption or decomposition of the Ru dye or catalyst.<sup>87</sup>

Following on from the cobaloxime system, a Co corrole catalyst synthesised by the Dey group demonstrated similar levels of O<sub>2</sub> tolerance in 2013 (**1B**, Fig. 6).<sup>80</sup> The study used a fluorinated macrocycle to decrease the overpotential needed for proton reduction and catalytic activity was established using a rotating ring-disk electrode consisting of the complex immobilised on an edge plane graphitic electrode with a Pt ring. Rotating ring-disk experiments were carried out in the presence of O<sub>2</sub>, allowing the authors to analyse the O<sub>2</sub> reduction by the Co corrole through oxidation of the generated H<sub>2</sub>O<sub>2</sub>. This demonstrated the real time reduction of protons to H<sub>2</sub> under aerobic conditions by the catalyst and CPE gave a FE of 52% under air after 10 hours of electrolysis in 0.5 M H<sub>2</sub>SO<sub>4</sub>. The O<sub>2</sub> tolerance of the Co corrole stems from its ability to reduce O<sub>2</sub> without deactivation, which had been reported previously.<sup>88</sup>

Bren and coworkers demonstrated in 2014 that an acetylated Co microperoxidase-11 complex (**1C**, Fig. 6) was O<sub>2</sub> tolerant.<sup>81</sup> This catalyst has a macrocyclic centre similar to that of **1B** and showed a high FE of 85% when CPE was carried out over 4 hours in a pH 7 solution (13% lower than the equivalent experiment under N<sub>2</sub>). The high FE seen in this case may be a result of the large applied overpotential (850 mV), making the barrier of proton reduction over O<sub>2</sub> reduction less significant. In such a case the relative concentrations of protons over O<sub>2</sub> would determine catalyst selectivity. At room temperature the concentration of O<sub>2</sub> is 0.3 mM under aerobic conditions<sup>89</sup> with a diffusion coefficient of 2 × 10<sup>-5</sup> cm<sup>2</sup> s<sup>-1</sup>,<sup>90</sup> and is therefore outmatched by the highly available and faster diffusing protons.

Cobalt polypyridyl catalysts have also demonstrated a degree of tolerance to O<sub>2</sub>. These catalysts typically show high stability towards deactivation and a number of structural variants have been synthesised.<sup>91,92</sup> [Co(*N,N*-bis(2-pyridinylmethyl)-2,2'-bipyridine-6-methanamine)(OH<sub>2</sub>)](PF<sub>6</sub>)<sub>3</sub> ([Co(DPA-Bpy)(OH<sub>2</sub>)](PF<sub>6</sub>)<sub>3</sub>) (**1D**, Fig. 6) is an O<sub>2</sub>-tolerant Co polypyridyl complex published by Zhao and coworkers.<sup>82</sup> Using a [Ru(bpy)<sub>3</sub>]<sup>2+</sup> photosensitiser in the presence of ascorbic acid as a sacrificial electron donor, the catalyst retained 40% of its activity in the presence of air, however this was not explored in more detail. This has been followed up by Lloret-Fillol and coworkers who used a 1,4-di(picolyl)-7-(*p*-toluenesulfonyl)-1,4,7-triazacyclononane (Py<sub>2</sub><sup>TS</sup>ta<sub>cn</sub>) ligand to form a Co complex capable of generating H<sub>2</sub> under O<sub>2</sub> (**1E**, Fig. 6).<sup>83</sup> In this case 25% of catalytic activity was maintained under air using a molecular Ir photosensitiser.

The O<sub>2</sub>-tolerant catalysts discussed thus far have a similar structure, consisting of N-ligating ligands to a Co centre. Proton reduction in such species is thought to occur through Co<sup>II</sup>/Co<sup>I</sup> intermediates to form a Co<sup>III</sup>-H.<sup>82,93,94</sup> The hydridic intermediate may then reduce a proton to form H<sub>2</sub> or be further reduced to Co<sup>II</sup>-H, which evolves H<sub>2</sub> (Fig. 8). Each of the reduced Co centres could also be active for O<sub>2</sub> reduction<sup>95,96</sup> (Fig. 8) and there is precedent for the formation of H<sub>2</sub>O<sub>2</sub> by cobaloximes<sup>24,97</sup> and H<sub>2</sub>O by Co corroles.<sup>88</sup> Proficient reduction of O<sub>2</sub> and ROS to harmless species by these catalysts may explain their limited deactivation in a similar manner to O<sub>2</sub>-tolerant hydrogenases. The catalytic core of these complexes is also comparable to Vitamin B12 and parallels can be drawn between the H<sub>2</sub> production and O<sub>2</sub> reduction activity of these species.<sup>96</sup> Comparison of these complexes to biological structures will be useful in understanding the effects of O<sub>2</sub> inhibition in both classes of catalyst.

Fig. 8 The proposed mechanism for heterolytic H<sub>2</sub> evolution from Co complexes **1A–E** and the potential O<sub>2</sub> reduction reactions that could be carried out at the reduced intermediates. Adapted from ref. 98.

Fig. 9 The O<sub>2</sub>-sensitive Ni bis(diphosphine) complex, **1F**, and the proposed route of inhibition. Complexes **1G** and **1H** are O<sub>2</sub> tolerant square planar Ni complexes.<sup>100</sup>

It is important for the study of O<sub>2</sub>-tolerant molecular complexes to move away from the Co–N based scaffold and branch out into different ligand structures and metal centres to establish other functionalities insensitive to deactivation. A recent study of O<sub>2</sub> tolerance with a Ni bis(diphosphine) catalyst (**1F**, Fig. 9) was consequently carried out by our group.<sup>79</sup> The cyclic phosphine ligand-set coordinated to Ni contains pendant amines, which serve as proton relays that has led to high activity in organic and aqueous solution.<sup>72,75</sup> CV of this hydrogenase-inspired catalyst showed little difference between anaerobic and aerobic conditions, however CPE at –0.4 V vs. NHE (0.13 V overpotential) at pH 4.5 produced 1.05 μmol of H<sub>2</sub> (72% FE) under N<sub>2</sub>, but no H<sub>2</sub> under 21% O<sub>2</sub>, indicating a high degree of O<sub>2</sub>-sensitivity.<sup>79</sup> In its native Ni<sup>2+</sup> oxidation state this catalyst is air stable, suggesting that a reduced form of the catalyst is susceptible to reaction with ROS/O<sub>2</sub>. The inactivation has been assigned to oxidation of the phosphine ligands to phosphine oxides during turnover under O<sub>2</sub> (Fig. 9), which show no proton reduction activity. This effect has been observed

when using compounds with similar composition as O<sub>2</sub> reduction catalysts.<sup>99</sup>

Recently two square planar Ni thiolate-containing complexes have shown a high degree of O<sub>2</sub> tolerance. These simple structures are notable for their high stability and in a recent report Eisenberg and coworkers showed that catalysts **1G** and **1H** (Fig. 9) exhibited TONs of 62 000 and 80 000, respectively, over 40 h CPE in aerobic solutions.<sup>100</sup> CVs of the catalysts were identical under Ar or air and CPE showed a 15–18% drop in FE between inert and aerobic conditions (93 to 78% for **1G** and 98 to 80% for **1H**). The high FE suggests that these catalysts are robust in air, which may be related to the high overpotential applied (between 700–800 mV), much like catalyst **1C**.

To gauge the current state of O<sub>2</sub>-tolerant molecular proton reduction catalysts, all examples known to us and their catalytic properties are summarised in Tables 1 and 2. In an ideal situation, H<sub>2</sub> would be produced at mild overpotentials, with the same rate and efficiency regardless of whether O<sub>2</sub> is present. This is not yet the case, however, examples continue to push the boundaries of what was previously thought possible and it appears that this could be realised within the next few years.

There are many other known molecular catalysts that should be studied under O<sub>2</sub> to establish a clear trend between catalyst structure and O<sub>2</sub>-tolerant proton reduction. It is also important that O<sub>2</sub>-tolerance studies are carried out in aqueous solution, rather than commonly used organic solvents as the solubility and behaviour of O<sub>2</sub> in these environments is drastically different (O<sub>2</sub> solubility in acetonitrile = 8.1 mM at 25 °C).<sup>101</sup> Computational studies have begun to establish the effects of O<sub>2</sub> on a molecular catalyst structure,<sup>102</sup> but further expansion and comparison to experimental data is required. Future investigation must also include the study of ROS intermediates and their interaction with metal complexes to establish the O<sub>2</sub> reduction tendencies of the O<sub>2</sub>-tolerant vs. the O<sub>2</sub>-sensitive catalysts. Nevertheless, at present it would seem that choosing a molecular catalyst capable of both catalytic O<sub>2</sub> and proton reduction is the most viable strategy to attain an O<sub>2</sub>-tolerant molecular system.

Table 1 Summary of CPE with O<sub>2</sub>-tolerant molecular catalysts and their H<sub>2</sub> production activity under O<sub>2</sub>

## 6. Oxygen-tolerant catalytic surfaces

'Catalytic surfaces' is a broad term that we apply to heterogeneous surfaces, nanoparticles and immobilised assemblies in this perspective. Given their generally high stability and amenability to widespread use, such surfaces have been able to produce large amounts of  $H_2$  at rates rivalling those of enzymatic systems and many new examples have recently emerged.<sup>15,103</sup> The wide scope for structural and geometric modification through methods such as doping, nanostructuring or controlled deposition of multifunctional layers has allowed rational surface design to maximise catalytic turnover and stability.<sup>12,104,105</sup> Their use includes a few disadvantages however, as they have generally low 'per atom activity' and ascertaining the exact nature of the catalytically active site and mechanism can be difficult.

Heterogeneous surfaces are considerably less sensitive to  $O_2$  than molecular complexes and hydrogenases (presumably due to the absence of fragile organic ligand frameworks) and many proton reducing surfaces are active  $O_2$  reduction catalysts.<sup>106,107</sup> New developments in this field are instead focused on increasing catalytic selectivity for  $H_2$  evolution over  $O_2$  reduction in order to maximise efficiency.

Surface engineering to exclude  $O_2$  diffusion to the active catalyst seeks to defend catalytic surfaces from  $O_2$  entirely. One example of  $O_2$  exclusion has been presented by Domen and coworkers on a photocatalytic water-splitting particle consisting of a  $(Ga_{1-x}Zn_x)(N_{1-x}O_x)$  photocatalyst loaded with Rh.  $O_2$  is particularly problematic in these systems as the Rh is able to catalyse the  $H_2$  and  $O_2$ -consuming back reaction of water splitting (the reverse of reaction 1).<sup>13</sup> It was found that the back reaction could be completely prevented through the use of a  $Cr_2O_3$  layer. When the Rh cocatalyst was coated with  $Cr_2O_3$  the water-splitting activity was greatly enhanced as the  $Cr_2O_3$  blocked  $O_2$  from diffusing to the Rh surface (Fig. 10a).<sup>108,109</sup> This effect was confirmed through a voltammetric study of a  $Cr_2O_3$ -coated Rh electrode, which showed complete loss of the  $O_2$  reduction wave on Rh.<sup>110</sup> Proton reduction activity still remained and was only slightly diminished as a result of the  $Cr_2O_3$  layer blocking some catalytic sites on the Rh. This was confirmed through infrared spectroscopy, which illustrated that protons were able to penetrate the  $Cr_2O_3$  to reach a catalytic Pt surface.

**Fig. 10** (a) Schematic representation of  $O_2$  exclusion by a  $Cr_2O_3$  layer loaded on a Rh cocatalyst for photocatalytic  $H_2$  production.<sup>110</sup> (b) Illustration of  $O_2$ -driven self-repair after photocorrosion of a  $CuRhO_2$  electrode to form inactive  $Cu^0$ .<sup>111</sup>

A similar strategy has been utilised by Dey and coworkers using ammonium tetrathiomolybdate (ATM),<sup>112</sup> a reagent commonly used as a precursor to  $H_2$ -evolving  $MoS_x$ . It was proposed that the ATM formed a layer on Au that could shuttle protons, whilst preventing access of  $O_2$  to catalytically active sites. CV of an ATM-Au electrode showed no  $O_2$  reduction wave and CPE with 180 mV applied overpotential under air gave a high FE of 89% for proton reduction over 10 hours. The oxygen tolerance of the  $MoS_x$  archetype is believed to originate from the S ligand, which plays a key role in the proton reduction mechanism.<sup>103</sup>

A number of other surface coatings have been able to prevent  $O_2$  reduction at photocatalyst surfaces, such as: lanthanide oxide layers based on La, Pr, Sm, Gd, and Dy on Rh loaded  $(Ga_{1-x}Zn_x)(N_{1-x}O_x)$ ;<sup>113</sup> amorphous Si and Ti oxyhydroxides on perovskite-type oxynitride,  $LaMg_xTa_{1-x}O_{1+3x}N_{2-3x}$  ( $x \geq 1/3$ );<sup>114</sup> surface-corroded  $Ti^{4+}$ -doped  $Fe_2O_3$ ;<sup>115</sup> electrodeposited amorphous  $TiO_2$  on W-doped  $BiVO_4$ ;<sup>116</sup> NiO-loaded on  $NaTaO_3$ <sup>117</sup> and cocatalysts of Au or  $RuO_2$ .<sup>12,118</sup>  $O_2$ -excluding  $SiO_2$  layers for electrocatalytic  $CO_2$  reduction have also emerged<sup>119</sup> and the presence of  $Li^+$  counter ions over  $K^+$  or  $Na^+$  has been shown to assist in the preclusion of  $O_2$  reduction.<sup>120</sup>

Other strategies to prevent a catalyst from  $O_2$  interaction may be achievable through  $O_2$ -impermeable polymers. Research in this field is well-established due to its amenability to industrial applications, such as  $O_2$ -impermeable packaging materials. A number of polymer layers are generally impermeable to  $O_2$  and thin coatings of metal oxides such as  $ZnO/SiO_x$  and Al can lower the  $O_2$  permeability further.<sup>121</sup>

Preventing  $O_2$  reduction can also be achieved through use of selective catalysts. Takanabe and coworkers have synthesised tungsten carbide nanoparticle cocatalysts that illustrate an affinity for proton reduction over  $O_2$  reduction catalysis.<sup>122</sup> Loading the nanoparticles onto a Na-doped  $SrTiO_3$  photocatalyst increased  $H_2$ -evolution activity and prevented  $O_2$  reduction, which led to the UV light-driven production of stoichiometric quantities of  $H_2$  and  $O_2$  through water splitting.

Alternatively,  $O_2$  in solution can be used to maintain a catalytic structure through  $O_2$ -driven self-repair. This has been demonstrated by Bocarsly and coworkers using a delafossite  $CuRhO_2$  structured electrode that functions most effectively under air (Fig. 10b).<sup>111</sup>  $O_2$ -driven self-repair is a form of  $O_2$  tolerance that reduces  $O_2$  to regenerate the active catalytic material.  $CuRhO_2$  is a photocathode for proton reduction at an applied bias of  $-0.7$  V vs. NHE in 1 M NaOH. Under inert atmospheres the surface is active for 3 hours of photoelectrolysis, whereas in an aerobic atmosphere the activity remained constant over 8 hours. The increased stability in the presence of  $O_2$  was proven *via* X-ray photoelectron spectroscopy to be a result of regeneration of  $Cu^I$  by dissolved  $O_2$ , which precluded the accumulation of  $Cu^0$  deposits on the surface. The material had a lowered FE compared to surfaces under inert atmospheres, at 80%, however this number is respectable in such challenging conditions and the lost efficiency is merely a result of the  $O_2$  reduction necessary for electrode regeneration.

In a similar example to the delafossite electrode above, a  $CuFeO_2$  electrode presented by Choi and coworkers was more

stable in the presence of  $O_2$ .<sup>123</sup> The surface was able to produce  $H_2$  under visible light with a very large applied bias of  $-1.4$  V vs. NHE in  $O_2$ -saturated 1 M NaOH. The electrode had a photon to current ratio of 2.2% under Ar saturated and 3.7% under  $O_2$  saturated solutions suggesting that the electrode was less selective towards  $H_2$  evolution than  $CuRhO_2$ . This has since been followed up by the Sivula group who described a sol-gel technique to fabricate a similar electrode,<sup>124</sup> which was further doped with  $O_2$  to improve performance.

Heterogeneous, proton-reducing surfaces offer the most simple and robust strategies to achieve  $O_2$ -tolerant  $H_2$  evolution. The use of  $O_2$ -excluding layers is particularly interesting as the approach is also amenable to the systems discussed in Sections 4 and 5 of this perspective. It should be noted that it is still rare for  $H_2$  evolution activity to be studied under aerobic conditions and more studies of the presented strategies in the presence of  $O_2$  are therefore necessary.

## 7. Conclusion and future outlook

This perspective describes the state-of-the-art for the rapidly developing field of  $O_2$ -tolerant proton reduction catalysis. Each of the catalytic classes discussed in Sections 4 to 6 demonstrate distinct approaches to achieve aerobic proton reduction, which revolve around either a defensive or an offensive strategy (Fig. 11). Future advances will surely involve a combined use of such techniques across enzymatic, molecular and surface-based catalysts, which we hope to bring together in this work.

Defensive methods to preclude  $O_2$  inhibition will allow the use of  $O_2$ -sensitive catalysts under less stringent conditions. The use of  $O_2$  shields offers a simple and effective approach to remove  $O_2$ , but such systems do not ensure complete elimination of  $O_2$  from a system and greatly lower catalytic efficiency.  $O_2$ -exclusion layers

are in theory a more effective route for  $O_2$ -sensitive systems as they generate an anaerobic environment for catalysis without reducing the overall efficiency. These would be particularly useful for highly  $O_2$ -sensitive catalysts, such as hydrogenases.

Offensive techniques utilise the catalytic centre to remove  $O_2$  from solution without damaging the catalyst and will be much simpler to utilise on a large scale.  $O_2$  tolerance has been identified in a number of catalysts and although not formally tested, is presumably present in a number of other species.  $O_2$  tolerance results in a lowered efficiency for proton reduction and decreasing the catalytic affinity for  $O_2$  reduction is therefore the predominant issue to be solved.  $O_2$ -tolerant systems can be further optimised through combination with defensive strategies, such as  $O_2$ -exclusion layers. Alternatively  $O_2$  can be used to improve the stability of reductively corroded catalysts through  $O_2$ -driven self-repair, taking advantage of oxidising aerobic atmospheres. This has proven particularly useful for delafossite structured catalysts and may also prove effective for other catalysts that decompose in inert atmospheres.

To make further progress in this field it is important that  $O_2$  inhibition becomes a more common test of a proton reduction system. A tolerance to  $O_2$  is an excellent trait for a catalyst to exhibit and should be reported alongside other catalytic properties. Establishing the impact of  $O_2$  is simple; a catalyst's interaction with  $O_2$  can be studied with an extra electrolysis or photolysis experiment under aerobic conditions rather than an inert atmosphere.

More in depth studies of  $O_2$ -tolerant catalyst systems should also become commonplace. Future studies would benefit from the use of rotating ring-disk electrodes and quantification of the produced ROS to help gain a better understanding of catalytic behaviour and deactivation pathways under air. Appreciating the factors that contribute to proton reduction inhibition by  $O_2$  should then pave the way for water splitting systems capable of functioning flawlessly under aerobic conditions. Whether such a system would be best implemented with an enzymatic, molecular or surface-based catalyst is yet to be determined, however the chemical strategies used to avoid  $O_2$  inhibition can mutually benefit the field as a whole.

The strategies considered in this perspective are also applicable to the production of other renewable fuels. Catalytic processes, such as  $CO_2$  reduction, offer alternate routes to artificial photosynthesis and would similarly benefit from  $O_2$ -tolerant catalysts (for high aerobic stability) in combination with  $O_2$ -exclusion strategies (for high efficiency). There are also other inhibitors to investigate, such as CO, which is formed in synthesis gas producing systems or through unwanted side reactions (e.g. in formic acid decomposition), the impact of which is seldom explored.<sup>79</sup> Understanding inhibition across a range of inhibitors and catalytic processes will have the dual benefit of increasing our understanding of catalytic active sites and increasing the viability of each system to more widespread production of sustainable, pollution-free fuel.

Fig. 11 A summary of the offensive/defensive strategies used to evolve  $H_2$  in the presence of  $O_2$ .
