Synthesis of enantiomerically pure $\delta$-benzylproline derivatives†

Isabel Rodríguez, M. Isabel Calaza, Ana I. Jiménez and Carlos Cativiela*

The (2S,5R) stereoisomer of $\delta$-benzylproline, i.e. the $\gamma$-proline analogue that bears a $\delta$-benzyl substituent cis to the carbonyl function, has been prepared in enantiomerically pure form and excellent global yield. The procedure involves the construction of the pyrrolidine ring through intramolecular cyclization and uses as starting material the enantiopure $\beta$-amino acid obtained by homologation of $\gamma$-phenylalanine. The generation of an intermediate vinyl triflate with full regiochemical control followed by a stereoselective hydrogenation reaction allowed the isolation of the target $\delta$-substituted $\gamma$-proline analogue in optically pure form and 43% overall yield from the initial $\beta$-amino acid. The trans stereoisomer of (2R,5S) configuration is obtained as a minor product through a less stereoselective hydrogenation reaction.

Introduction

One of the most efficient approaches to control peptide conformation is the incorporation of amino acids with restricted conformational flexibility into the peptide chain. Among proteinogenic residues, only proline exhibits clearly defined conformational propensities.1 This is due to the presence of the five-membered pyrrolidine ring that includes the $\alpha$ carbon and the amino function, thus precluding rotation around the N–Cα bond. As a consequence, proline cannot adopt the fully extended conformation and acts as a turn inducer in peptide chains.1,2 Another effect associated to the cyclic nature of proline is the relative high probability of the so-called prolyl peptide bond (that formed by the pyrrolidine nitrogen and the carbonyl group of the preceding residue) to accommodate a cis arrangement.1,3

The singular structure of proline may serve as a scaffold for the construction of new amino acids with well-defined conformational tendencies and, indeed, extensive research has been conducted on the synthesis of proline analogues with different types of modifications.4,5 In particular, the attachment of substituents to the pyrrolidine cycle gives rise to non-proteinogenic residues that should retain the conformational propensities of the natural amino acid while incorporating new side-chain functionalities. Such a combination of structural and functional properties makes substituted prolines very helpful to stabilize structural motifs in peptides and is particularly appealing in the case of proline analogues that bear side chains belonging to other proteinogenic amino acids. Moreover, by adequately choosing the position, nature, and steric bulk of the new substituent incorporated, the conformational propensities of the parent amino acid may be adjusted.5,6

In this regard, attachment of a substituent to the $\delta$ position of the pyrrolidine cycle (C-5) affects the cis-trans isomerization state of the prolyl peptide bond,5,6 which is governed by steric interactions of the acyl moiety linked to the pyrrolidine nitrogen with the contiguous $\alpha$ and $\delta$ positions of the pyrrolidine cycle. Thus, proline analogues with considerable steric hindrance at C8 such as $\delta$-$\delta$-dimethylproline and $\delta$-tert-butyldimethoxycarbonylproline have been shown to stabilize the cis state of this peptide bond,7 which, in turn, affects the overall conformation of the peptide backbone. The possibility to modulate amide geometry by using $\delta$-substituted prolines has been applied, for example, to investigate the folding pathways of therapeutic proteins8 to elucidate the receptor-bound conformation of bioactive peptides,9,10 or to establish the role of amide cis-trans isomerization of a single proline residue in switching the open/closed states of a neurotransmitter-gated ion channel.10 Moreover, several proline analogues containing aromatic substituents at the $\delta$ position have been used in the design of peptide-based pharmacologically active compounds.11 Among these analogues is $\delta$-benzylproline,11 which combines the conformational constraints of proline with the side chain of phenylalanine. This proline–phenylalanine hybrid amino acid may not only provide fundamental insights into the precise conformational requirements for optimal receptor binding affinity in bioactive peptides, but can also be very useful to understand the influence of...
by a metal carbenoid and further functionalization of the intermediate β-ketoproline formed to incorporate the aromatic substituent. We subsequently showed that the procedure is applicable to the β-alanine derivative possessing two geminal methyl groups at C-3, which enabled the synthesis of δ,δ-dimethyl-β-phenylproline and δ,δ-dimethylproline. In both cases, non-chiral β-amino acids were used as substrates and the substituted proline analogues were obtained in racemic form. Yet the procedure should be adequate for the preparation of enantiother ther pure prolines with different substitution patterns by using homochiral β-amino acids as starting materials. In particular, we envisioned that the enantiopure β-amino acids readily accessible from proteinogenic 1-amino acids through well-known racemization-free homologation procedures (many of them are also commercially available) could allow the synthesis of optically pure δ-substituted prolines that incorporate the side chain of the coded amino acid at the δ position (Scheme 2). The validity of this hypothesis was checked by addressing the preparation of enantiother ther pure δ-benzylproline starting from the β-amino acid derived from 1-phenylalanine. To the best of our knowledge, no β-amino acid of this type has been used to date for the synthesis of δ-substituted proline derivatives.

The synthetic route began with the preparation of the desired β-amino acid bearing a tert-butoxycarbonyl (Boc) group at the amino function as this type of protection is widely used in standard peptide synthesis and is compatible with the synthetic transformations to be carried out. This compound, Boc-β-homophenylalanine or (S)-3-(N-tert-butoxycarbonyl)amino-4-phenylbutanoic acid, is available from commercial sources albeit at a very high price. Alternatively, it can also be obtained in multigram quantities and optically pure form by Arndt–Eistert homologation of non-expensive Boc-L-phenylalanine following the well-established literature procedure. We applied a slightly modified version of this method. Thus, the mixed anhydride generated by reaction of Boc-L-phenylalanine with ethyl chloroformate was treated with trimethylsilyldiazomethane (Scheme 3) instead of the very hazardous diazomethane to form the

Results and discussion

We have recently shown that β-amino acids are suitable precursors for the synthesis of racemic proline analogues substituted at the β and/or δ positions of the pyrroline ring. Thus, we carried out the preparation of racemic β-phenylproline by cyclization of an α-diazo-β-ketoester derived from β-alanine through an intramolecular N–H insertion reaction mediated
cis-mixture of d delivered the N–H insertion reaction of the metal carbenoid generated in situ diacetate catalysis under heating conditions. The intramolecular azide in the presence of triethylamine. The resulting transfer reaction by treatment with 4-(acetamido)benzenesulfonyl decarboxylation. The crude compound was subjected to a diazo-derived soft enolate to afford the diimidazole and the imidazolide formed reacted with a malonate-double bond connecting the regioselective manner so that only the regioisomer with a base and triflating agent, we have established the conditions methanesulfonate, OTf). By using the adequate combination of tion through an intermediate vinyl triflate (triflate: trifluoroacid 2 applied by Sorensen to (Scheme 4). To this end, we followed the experimental procedure underwent a rearrangement process promoted by silver trimethylsilyldiazomethane (Scheme 3). Next, the diazoketone was obtained in good yield using the stable and less hazardous trimethylsilyldiazomethane in the presence of triethylamine. The resulting α-diazo-β-ketoester (4) underwent decomposition promoted by rhodium diacetate catalysis under heating conditions. The intramolecular N–H insertion reaction of the metal carbenoid generated in situ delivered the δ-benzyl-β-ketoproline derivative 5 as an inseparable mixture of cis/trans stereoisomers. This mixture was obtained in 72% overall yield from the starting β-amino acid (2) with a single purification being necessary.

The final step in the route to the target amino acid involved reduction of the ketone function at the β position (C-3) in 5. In our previous syntheses of substituted proline analogues starting from β-amino acids, we carried out this transformation through an intermediate vinyl triflate (triflate: trifluoromethanesulfonate, OTf). By using the adequate combination of base and triflating agent, we have established the conditions for the formation of this intermediate triflate in a completely regioselective manner so that only the regioisomer with a double bond connecting the α and β carbons (C-2, C-3) is obtained. Accordingly, there are two reasons to prefer the formation of this intermediate vinyl triflate over other methodologies for the reduction of the carbonyl moiety at C-3 in compound 5. First, as the intramolecular cyclization reaction giving rise to 5 (Scheme 4) proceeds with low diastereoselectivity, hydrogenation of the double bond in this triflate provides a further opportunity to obtain the desired δ-benzylproline with a higher degree of stereocontrol at the α carbon. Second, if desired, the triflate moiety at the β carbon may serve for the incorporation of additional substituents at this position, as demonstrated in our previous work.

Therefore, we undertook the generation of the vinyl triflate (Scheme 5) by applying the combination of base and triflating agent that proved essential to achieve full regiocontrol when dealing with other 3-ketoproline derivatives previously investigated. Thus, deprotonation of 5 (mixture of cis/trans diastereoisomers) with potassium bis(trimethylsilyl)amide (KHMDS) gave an enolate that was trapped with N-(5-chloro-2-pyridyl)triflimide (Comins’ reagent) to yield 6 as a single regioisomer. Compound 6 proved stable enough for chromatographic purification and when stored at −20 °C.

With the aim to obtain the desired δ-benzylproline, triflate 6 was first subjected to a palladium-catalyzed reductive removal

of the triflate moiety using triethylsilane as the hydride source (Scheme 5). The resulting α,β-dehydroproline derivative (7) was then submitted to hydrogenation to generate the saturated five-membered ring. Treatment of 7 with hydrogen gas at atmospheric pressure in the presence of palladium on carbon as a catalyst proceeded with quantitative yield but only moderate diastereoselectivity, so that a 73:27 mixture of δ-benzylprolinates 8 was formed (Scheme 5), as deduced from the 1H-NMR spectrum. The 8 diastereoisomers could not be separated by column chromatography and, therefore, their cis/trans relative configuration [corresponding, respectively, to a (2S,5R)/(2R,5R) absolute stereochemistry29] was not established at this stage. Yet a cis relative disposition of substituents around the pyrrolidine ring, and hence a (2S,5R) absolute configuration, was tentatively assigned to the major diastereoisomer assuming that hydrogenation had preferentially taken place on the less hindered face of the molecule, that is, opposite the benzyl substituent. Luckily enough, chromatographic separation of diastereoisomers was possible after removal of the Boc group of the (2R,5R)-8 mixture under standard acidic conditions (Scheme 5). For characterization purposes, samples of the pure amino esters thus isolated, (2S,5R)-9 and (2R,5R)-9, were transformed into the corresponding N-Boc-protected precursors, (2S,5R)-8 and (2R,5R)-8, respectively (Scheme 5). In this way, the (2S,5R) and (2R,5R) stereoisomers of 8 and 9 were obtained in optically pure form.29

The stereochemistry of the enantiomerically pure 8 and 9 δ-benzylprolinates obtained (Scheme 5) was first established by 2D NOESY experiments performed on the amino esters. A NOE correlation was observed between the α and δ protons only for the major 9 stereoisomer, indicating a cis relative disposition of the benzyl and carboxylate substituents in this compound, that is, a (2S,5R) absolute configuration. This result is in agreement with the stereoselectivity expected for the hydrogenation process. The stereochemical assignment was corroborated by X-ray diffraction analysis of single crystals of the N-acetyl derivative obtained by reaction of the minor amino ester with acetic anhydride (Fig. 1). The R configuration at C-5, given by the starting β-amino acid derived from l-phenylalanine, was taken as a reference in these assignments.

In the search for a more selective, and hence efficient, procedure for the synthesis of (2S,5R)-δ-benzylproline, compound 6 was treated directly with hydrogen gas at atmospheric pressure using palladium on carbon as a catalyst. Under these conditions, removal of the triflate group and reduction of the olefin moiety occurred to cleanly afford a mixture of δ-benzylprolinates 8 (Scheme 5). The combined yield of (2S,5R)-/(2R,5R)-8 isolated was substantially higher (97% vs. 67% when obtained through the intermediate Δ2-pyrrolidine 7) but, unfortunately, the same 73:27 ratio of cis/trans diastereoisomers was determined in the 1H-NMR spectrum of the crude product.30 Therefore, the direct 6 to 8 transformation allowed the isolation of the major δ-benzylproline (2S,5R)-9 [as well as the minor (2R,5R)-9 stereoisomer] with significantly improved yield and avoiding one synthetic step. Accordingly, the synthesis of the intermediate 7 had no advantage in the route to the target δ-benzylprolinates 8/9. Even so, it should be noted that compound 7 is an enantiomerically pure α,β-dehydroproline derivative that may be useful as such for different types of studies. Moreover, 7 is also an interesting intermediate for the preparation of δ-benzylprolinates with further functionalization at the β (and α) position(s) taking advantage of the reactivity of the endocyclic conjugated double bond. The same holds true for 6, whose triflate moiety could enable the incorporation of additional substituents at the β carbon by means of cross-coupling reactions.16

In a further attempt to increase the diastereoselectivity of the process, the catalytic hydrogenation of triflate 6 was explored under different conditions. When palladium on carbon was replaced by platinum oxide, the cis 8 diastereoisomer, (2S,5R)-8, was formed with higher diastereoselectivity, with only a small amount of the trans stereoisomer being detected in the 1H-NMR spectrum of the crude product.31 In this way, after removal of the Boc group, the pure cis amino ester, (2S,5R)-9, was obtained in 85% yield from 6 (Scheme 6). This modification therefore allowed the synthesis of enantiomerically pure δ-benzylproline (2S,5R)-9 in 43% overall yield from the initial β-amino acid (2). This δ-benzylproline derivative is ready for functionalization at the amino terminus while the corresponding N-Boc-protected amino acid suitable for standard peptide synthesis could be easily obtained following the procedure used for other proline analogues.12

The results described above show that the β-amino acid derived from l-phenylalanine allows the efficient synthesis of the l-proline analogue (S configuration at Cα or C-2) that bears a δ-benzyl substituent cis to the carboxylate moiety [(2S,5R)-8/9 in Schemes 5 and 6]. In principle, this procedure should be extensible to β-amino acids derived from other proteinogenic amino acids (available from commercial sources or by well-known stereocontrolled homologation procedures20) thus providing access to enantiomerically pure cis δ-substituted l-proline analogues that contain the side chain of such ceded

amino acids at the δ position (note that the diastereoselectivity of the hydrogenation reaction may depend, to a great extent, on the nature of the substituent at Cδ and therefore differ from that observed in this work for the L- phenylalanine derivative). The present methodology therefore complements that developed by Davis, which has proven successful for the preparation of enantiopure δ-substituted prolines of the same configuration (cis δ-substituted L-prolines) with other types of substituents, namely aryl, vinyl, or tert-butyl (in general, those derived from aldehydes with no hydrogen at the α position or possessing a non-enolizable α hydrogen) but would not be adequate when the substituent at Cδ is the side chain of a proteinogenic amino acid. In all such cases the aldehyde to be used as the starting material has an enolizable α hydrogen and the chiral sulfonime formed would be susceptible to the imine-enamine equilibrium leading to epimerization at the stereogenic centre that corresponds to C-5 in the final δ-substituted proline, thus hampering the isolation of enantiopure compounds.

Conclusions

A convenient procedure has been developed for the preparation of an enantiomerically pure L-proline analogue characterized by a δ-benzyl substituent cis to the carboxylate moiety. The fragment of the pyrrolidine ring bearing the benzyl group derives from L-phenylalanine. Thus, the synthetic route starts with the β-amino acid obtained by homologation of L-phenylalanine and involves the construction of a 3-oxopyrrolidine through an intramolecular cyclization reaction. The formation of an intermediate vinyl triflate with complete regioselectivity and involves the construction of a 3-oxopyrrolidine through an intramolecular cyclization reaction. The formation of an intermediate vinyl triflate with complete regioselectivity and good diastereoselectivity attained in the subsequent hydrolysis of this compound using platinum oxide as a catalyst have allowed the isolation of the final cis δ-substituted L-proline derivative, methyl (2S,5R)-5-benzylprolinolactone, in enantiomerically pure form and 43% overall yield. If desired, the corresponding trans stereoisomer, methyl (2R,5R)-5-benzylprolinolactone, can be isolated as a minor product through a less diastereoselective palladium-catalyzed hydrogenation reaction. Clearly, starting from L-phenylalanine, the (2R,5S) and (2S,5S) stereoisomers would be obtained as major and minor products, respectively. The procedure could be adequate for extension to β-amino acids derived from proteinogenic residues other than L-phenylalanine, thus allowing the synthesis of enantiomerically pure δ-substituted proline analogues bearing the side chain of different coded amino acids at the δ carbon. This methodology complements other previously described methods for the synthesis of enantiopure or highly enanti-enriched δ-substituted prolines.

Experimental

Single-crystal X-ray diffraction

Colourless single crystals of (2R,5R)-10 were obtained by slow evaporation of a solution in dichloromethane–hexanes. The X-ray diffraction data were collected at 295 K on an Oxford Diffraction Xcalibur diffractometer provided with a Sapphire CCD detector, using graphite monochromated Mo-Kα radiation (λ = 0.71073 Å). The structure was solved by direct methods using SHELSX-97 and refinement was performed using SHELXX-97 by the full-matrix least-squares technique with anisotropic thermal factors for heavy atoms. Hydrogen atoms were located by calculation and affected by an isotropic thermal factor fixed to 1.2 times the equivalent isotropic displacement parameter. The crystal data are given in Table 1.

Syntheses

General. All reagents were used as received from commercial suppliers without further purification. Thin-layer chromatography (TLC) was performed on Macherey-Nagel Polygram SIL G/UV254 precoated silica gel polyester plates. The products were visualized by exposure to UV light, iodine vapour, submergence in ninhydrin stain or in ethanolic solution of phosphomolybdic acid. Column chromatography was performed using 60 M (0.04–0.063 mm) silica gel from Macherey-Nagel. Melting points were determined on a Gallenkamp apparatus. IR spectra were registered on a Nicolet Avatar 360 FTIR spectrophotometer; νmax is given for the main absorption bands. 1H and 13C NMR spectra were recorded on a Bruker ARX-300, AV-400 or AV-500 instrument at room temperature, unless otherwise indicated, and using the residual solvent signal as the internal standard; chemical shifts (δ) are expressed in parts per million and coupling constants (J) in hertz. Optical rotations were measured at room temperature using a JASCO P-1020 polarimeter. High-resolution mass spectra were obtained on a Bruker MicroTOF-Q spectrometer.

5a,8a-Diazabicyclo[5.4.0]undec-9-ene, 1. To a stirred solution of N-Boc-L-phenylalanine (2.50 g, 9.42 mmol) in anhydrous tetrahydrofuran (60 mL) at −15 °C, triethylamine (1.57 mL, 11.30 mmol) and ethyl chloroformate (1.08 mL, 11.30 mmol) were sequentially added. The mixture was stirred at −5 °C for 30 min. The precipitated triethylammonium chloride was filtered off, the solvent was evaporated and the residue obtained was dissolved in acetonitrile (30 mL). The solution was cooled to 4 °C and a 2 M solution of (trimethylsilyl)diazomethane in diethyl ether (9.42 mL, 18.84 mmol) was added slowly using a syringe. The reaction mixture was stirred at the same temperature for 24 h. After that, diethyl ether was added (20 mL) and the mixture was washed with 10% aqueous citric acid (3 × 50 mL), saturated aqueous NaHCO3 (2 × 50 mL) and brine (2 × 50 mL). The organic layer was dried over anhydrous MgSO4, filtered and evaporated to dryness. The residue was purified by column chromatography (eluent: ethyl acetate/hexanes 2:3) to give diazoketone 1 as a slightly yellow solid.
(2.37 g, 8.19 mmol, 87% yield). Spectroscopic data were identical to those reported.\(^{20}\)

(S)-3-(N-tert-Butoxycarbonyl)amino-4-phenylbutanoic acid, 2.

To a solution of diazoketone 1 (2.10 g, 7.26 mmol) in dioxane/water (3:1 v/v, 100 mL), sodium carbonate (769 mg, 7.26 mmol) and silver benzoate (42 mg, 0.18 mmol) were added. The resulting suspension was sonicated for 45 min in an ultrasonic bath. The silver salts were filtered off and the reaction mixture was diluted with water and washed with diethyl ether (2 × 60 mL). The aqueous phase was acidified to pH 2 with 1 M HCl and extracted with ethyl acetate (3 × 80 mL). The combined organic layers were dried over anhydrous MgSO\(_4\), filtered and evaporated under reduced pressure. The resulting residue was purified by column chromatography (eluent: hexanes/ethyl acetate 1:1 containing 1% acetic acid) to afford 2 as a white solid (1.75 g, 6.26 mmol, 86% yield). \[^1\]H NMR (400 MHz, CDCl\(_3\)) \(\delta\) 1.40 (9H, s), 2.33 (1H, m), 2.65 (1H, m), 2.94 (1H, m), 3.25 (1H, m), 3.74 (3H, s), 4.43 (1H, m), 4.70 (1H, s), 7.00–7.42 (5H, m). \[^13\]C NMR (100 MHz, DMSO-d\(_6\), 373 K) (only signals of the major diastereoisomer are listed): \(\delta\) 27.4, 40.6, 41.6, 51.9, 55.0, 65.3, 79.7, 125.8, 127.9, 128.6, 137.5, 152.2, 166.6, 203.5. Methyl (25,5R)-5-benzylpyrrolidine-2-carboxylate, (25,5R)-9. A mixture of 6 (100 mg, 0.22 mmol), sodium carbonate (12 mg, 0.11 mmol) and PtO\textsubscript{2} (1.50 mg) in methanol (2 mL) was stirred for 1 h at room temperature under hydrogen gas at atmospheric pressure. The catalyst was filtered off and washed with methanol. The solvent was evaporated under reduced pressure. The residue was dissolved in dichloromethane (3 mL) and washed with water. The organic layer was dried over MgSO\textsubscript{4}, filtered and evaporated under reduced pressure. The residue was purified by column chromatography (eluent: ethyl acetate:hexane 1 : 2) to afford (25,5R)-9 as an oil (40 mg, 0.18 mmol, 85% yield). Spectroscopic data were identical to those described above.

Methyl (25,5R)-5-benzylpyrrolidine-2-carboxylate, (25,5R)-9. A solution of (25,5R)-9 (50 mg, 0.23 mmol) in dichloromethane (5 mL) was treated with di-tert-butyldicarbonate (75 mg, 0.34 mmol). After stirring at room temperature for 1 h, the mixture was washed with water (2 × 5 mL) and brine (2 × 5 mL). The organic layer was dried over MgSO\textsubscript{4}, filtered and evaporated under reduced pressure. The residue was purified by column chromatography (eluent: ethyl acetate:dichloromethane 7 : 3) to afford (25,5R)-9 (40 mg, 0.18 mmol, 85% yield). Spectroscopic data were identical to those described above.

Methyl (25,5R)-N-(tert-butoxycarbonyl)-5-benzylpyrrolidine-2-carboxylate, (25,5R)-9. A solution of (25,5R)-9 (31 mg, 0.14 mmol) in chloroform (2 mL) was treated with sodium acetate (35 mg, 0.42 mmol) and acetic anhydride (40 μL, 0.42 mmol). After stirring at room temperature for 4 h, the mixture was washed with saturated aqueous NaHCO\textsubscript{3} (2 × 5 mL) and brine (2 × 5 mL). The organic layer was dried over MgSO\textsubscript{4}, filtered and evaporated under reduced pressure. The residue was purified by column chromatography (eluent: hexanes/ethyl acetate 3 : 1) to afford (25,5R)-9 as an oil (70 mg, 0.22 mmol, 96% yield). \left[\delta_{27}^{13}C = 55.9 \text{ (c 0.32 in CHCl}_3\text{). IR (neat) } \nu_{\text{max}}^{\text{IR}} \right.

Notes and references

24 The specific rotation was in agreement with that reported in ref. 20: see Experimental section.

26 The 1H-NMR spectrum of the purified (2R,5S)-5 mixture showed broadened, partially overlapped signals even when registered at high temperature. Under the best conditions ($^1H$-NMR in DMSO-$d_6$ at 373 K), the ratio of 5 diastereoisomers was roughly estimated to be $\approx 2.2:1$. A more precise determination of this ratio was not considered essential, and therefore was not addressed, since this
mixture of epimers at the α carbon would be transformed into the same compound subsequently in the synthesis. For the same reasons, identification of the cis/trans diastereoisomers in the mixture was not made.

28 Formation of the regioisomer with a double bond connecting C-3, C-4 was not observed. In our previous work (ref. 16a), the use of triflic anhydride or N-phenyltriflimide with this or other bases (as LiHMDS) led to mixtures of the desired vinyl triflate and the regioisomer exhibiting a double bond at C-3, C-4.

29 Note that the configuration at C-5 (C8) is given by the starting homochiral β-amino acid while that at the α carbon (C-2) is generated in the hydrogenation process. In this regard, it is important to emphasize that the reaction conditions in Schemes 4 and 5 should not compromise the configurational integrity of the chiral carbon attached to the benzyl substituent in the initial β-amino acid (C-5 in the final δ-benzylprolinates), thus leading to enantiomerically pure compounds after separation of diastereoisomers. Even so, the enantiomeric purity of (2S,5R)-8 and (2R,5R)-8 was checked by HPLC analysis on six different chiral columns (Chiralpak® IA, IB, IC, ID, IE, and IF) eluting with n-hexane–2-propanol mixtures and a single peak was observed in all assays. Given the high enantiodiscrimination ability typically shown by these chiral stationary phases, the absence of a peak attributable to the other enantiomer in all of the chromatograms registered strongly supports the enantiomeric purity of the compounds analyzed, (2S,5R)-8 and (2R,5R)-8, and their precursors, (2S,5R)-9 and (2R,5R)-9.

As a matter of fact, we have tested a great number of N- and C-protected non-proteinogenic amino acids on these columns (particularly, the IA, IB, and IC types, which have been on the market for some years) and never found a case in which separation of enantiomers was not observed on at least one of them. For some examples of enantioseparation of proline analogues on Chiralpak® IA, IB, or IC columns, see ref. 4b and 16b and (a) P. Fatás, A. M. Gil, M. I. Calaza, A. I. Jiménez and C. Cativiela, Chirality, 2012, 24, 1082–1091; (b) F. J. Sayago, A. I. Jiménez and C. Cativiela, Tetrahedron: Asymmetry, 2007, 18, 2358–2364; (c) F. J. Sayago, M. J. Pueyo, M. I. Calaza, A. I. Jiménez and C. Cativiela, Chirality, 2011, 23, 507–513; (d) A. M. Gil, E. Buñuel, P. López and C. Cativiela, Tetrahedron: Asymmetry, 2004, 15, 811–819.

30 The identical diastereoselectivity observed is not completely unexpected since this transformation has been proposed to occur through hydrogenolysis of the C–O bond followed by hydrogenation of the alkene: A. García Martínez, R. Martínez Álvarez, J. Arranz Aguirre and L. R. Subramanian, J. Chem. Soc., Perkin Trans. 1, 1986, 1595–1598.

31 The presence of some impurities hampered precise determination of the diastereomeric ratio.

32 If desired, the N-Boc-protected amino acid could be obtained by treatment of (2S,5R)-8 [generated by introduction of the Boc group on (2S,5R)-9 as shown in Scheme 5] with lithium hydroxide in methanol–water. These conditions have proven efficient for deprotection of the methyl ester function in other substituted proline analogues while being mild enough to preserve the optical purity of the substrate: see ref. 29a.
