Unsupported thiolate-capped palladium nanoparticle catalysts are found to be highly substrate-selective for alkene hydrogenation and isomerization. Steric and poisoning effects from thiolate ligands on the nanoparticle surface control reactivity and selectivity by influencing alkene adsorption and directing either di- $\sigma$  or mono- $\sigma$  bond formation. The presence of overlapping p orbitals and  $\alpha$  protons in alkenes greatly influences the catalytic properties of deactivated palladium nanoparticles leading to easily predictable hydrogenation or isomerization products.

## Introduction

Alkene transformation reactions significantly impact industrial processes, including those utilized for pharmaceutical, polymer, and petrochemical synthesis.<sup>1,2</sup> Diene transformations represent an especially interesting problem due to the similar reactivity of both alkenes.<sup>3,4</sup> To overcome this problem, synthetic methods utilizing alkene masking and modification of the other alkene followed by demasking have been demonstrated.<sup>5–8</sup> Despite the value of these methods, protection-deprotection is generally atom inefficient and lengthens synthesis by at least two steps. In terms of catalytic hydrogenation, metal complexes such as Wilkinson's<sup>9,10</sup> or Crabtree's<sup>11,12</sup> catalysts and various Pd complexes<sup>13–15</sup> are very efficient for regioselective or chemoselective hydrogenation. However, their ligand dissociation mechanism and the risk of residue metal toxicity limit their modern synthetic utility,<sup>16,17</sup> especially in pharmaceutical applications. Palladium based catalytic materials circumvent some of these challenges and have been adopted by many industries.<sup>1,2</sup> One of the most challenging problems associated with palladium, however, has been the poisoning and deactivation of these materials.<sup>18–21</sup>

Recently, the use of nanomaterials as catalysts gained significant attention owing to their enhanced catalytic activity and recyclability. Many groups have taken advantage of functionalized supports and ligands or designer surfactants to tune the properties of various nanomaterials.<sup>22,23</sup> Our laboratory demonstrated that the catalytic activity and recyclability of

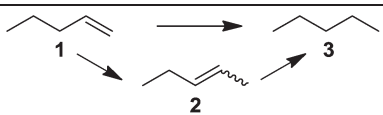

palladium nanoparticles (PdNP) can be controlled with thiolate-capping agents by selectively converting allyl alcohol to propanal *via* isomerization instead of 1-propanol *via* hydrogenation.<sup>24–26</sup> Our previous work also demonstrated that the isomerization mechanism occurs through  $\pi$  coordination followed by the formation of a mono- $\sigma$  Pd-alkyl intermediate.<sup>27,28</sup> With this type of mechanism in mind, the application of these PdNP catalysts for alkene transformation reactions is further exploited. Herein, this paper reports a new discovery showing the influence thiolate ligands on PdNP surfaces have on substrate adsorption and surface hydrogen reactivity, leading to selective hydrogenation or isomerization of dienes and monoenes.

## Results and discussion

Supported bare PdNPs and various Pd complexes are known to hydrogenate pentene isomers (Table 1).<sup>29–33</sup> It is well known that higher alkenes such as pentene are known to only undergo complete hydrogenation *via* the di- $\sigma$ -bonded species on palladium surfaces.<sup>34,35</sup> However, when 1-pentene (**1**) was subjected to unsupported, octanethiolate-capped PdNP ( $2.6 \pm 1.1$  nm, 0.52 surface ligands/Pd surface atoms) in  $\text{CDCl}_3$  under  $\text{H}_2$  conditions for 24 h, the isomerization product (2-pentene, **2**) with only minimal amounts of pentane (**3**) was observed (entry 1). When  $\text{H}_2$  was replaced with  $\text{N}_2$  as a control experiment, the catalytic conversion of 1-pentene did not occur (entry 2).  $\text{SiIPdCl}_2$  is the only catalyst with somewhat similar catalytic activity to PdNP (entry 5), however it completely loses its catalytic ability upon exposure to air.<sup>31</sup> The lack of reaction in the absence of  $\text{H}_2$  shows that isomerization cannot be due to the  $\pi$  allyl mechanism because that reaction mechanism

does not require H<sub>2</sub> to proceed. Instead, isomerization of 1-pentene (**1**) on these PdNPs must occur through the mono-σ bonded Pd-alkyl intermediate followed by β-hydride elimination as we previously proposed.<sup>27,28</sup> This mechanism is consistent with *trans*-2-pentene hydrogenation on Pd/Al<sub>2</sub>O<sub>3</sub> under ultrahigh-vacuum conditions.<sup>34</sup> Since **2** reluctantly reacted with thiolate-capped PdNP, it is likely that the thiolate ligands are preventing the di-substituted alkene from forming the prerequisite di-σ-bonded species for hydrogenation. On large supported bare PdNP catalysts, catalytic activity is heavily reduced over time because the alkene substrate forms too many strong di-σ-bonded species on the catalytic surface.<sup>18,19</sup> The thiolate capping agents on our PdNP catalyst help reduce substrate oversaturation, thereby limiting the poisonous effects.<sup>27,28</sup> The presence of partial PdS<sub>x</sub> layer on the surface of PdNP after thiolate monolayer formation, which has been observed by others, might also be the reason for deactivation of PdNP catalyst.<sup>36</sup>

To understand whether hydrogenation could be forced to occur by blocking isomerization (Table 2), 3,3-dimethylbut-1-ene (**4**) and styrene (**6**) were subjected to PdNP under H<sub>2</sub> conditions. No reaction between PdNP and **4** took place (entry 1) while **6** was completely converted to ethylbenzene (entry 2). Even though styrene's steric bulk is quite considerable, the p orbitals and planar geometry of the benzene ring must be aiding di-σ-bond formation, which allows hydrogenation to proceed. Comparatively, the *t*-butyl group in **4** does not contribute to, but hinders di-σ-bond formation, preventing hydrogenation to take place. The effect of substitution pattern around nonaromatic sp<sup>2</sup> carbons was also studied using isomers of stilbene. Under the same reaction conditions, both *trans*-stilbene (**8**) and *cis*-stilbene (**10**) were hydrogenated to 1,2-diphenylethane (**9**) with 4% and 9% conversion, respectively. While no isomerization of **8** was observed (entry 3), partial isomerization (29%) of **10** to **8** (*cis* to *trans*) clearly took place (entry 4). Concerned that the isomerization of **10** was taking place due to ambient light,<sup>38–40</sup> a control experiment without PdNP was performed and no isomerization resulted. By extending the reaction time to 48 h with additional H<sub>2</sub> after 24 h, **10** was converted to a mixture of 54% isomerization

<sup>a</sup> Reaction conditions: 50 mL round bottom flask, alkene (0.5 mmol), PdNP (5 mol%), CDCl<sub>3</sub> (2.5 mL), H<sub>2</sub> (1 atm), 24 h. <sup>b</sup> No PdNP was used.<sup>c</sup> 48 h reaction time with H<sub>2</sub> added after first 24 h.

product (**8**) and 21% hydrogenation product (**9**) (Fig. S3†). Because of stilbenes (**8** and **10**) being bulkier than styrene (**6**), the extended p orbital overlap from two benzene rings would not be enough to allow **8** and **10** to be hydrogenated with higher conversion. Furthermore, the preference of isomerization over hydrogenation for **10** is strongly indicative of the formation of mono-σ bonded Pd-alkyl species. As the steric bulk of these species increases, the addition of the second H atom must be slower than the isomerization of *cis* to *trans* on PdNP surface.

Further expansion of the substrate scope of the thiolate-capped PdNPs was attempted using cyclic alkenes (Table 3). First, the hydrogenation of cyclohexene (**11**) was examined and as expected, only a low 5% conversion to cyclohexane (**12**) was obtained (entry 1). In the case of 1,4-cyclohexadiene (**13**), 33% conversion to **11** resulted (entry 2). Its isomerization product, 1,3-cyclohexadiene, was not observed. This is likely due to the near planar geometry of **13** which allows all of its p-orbitals to contribute to di-σ bond formation. Instead of forming the mono-σ bonded species and undergoing isomerization, this geometry makes the direct addition of both H atoms possible. Conjugation with carbonyls was also considered. For 2-cyclo-

hexenone (15), only the alkene was expected to be hydrogenated because thiolate-capped PdNPs are not active enough to reduce carbonyls.<sup>24–26</sup> Indeed, 15 underwent 83% conversion to cyclohexanone (16) (entry 3). Similarly, maleic anhydride (17) was hydrogenated to succinic anhydride (18) with 64% conversion after 24 h. Extending the reaction time to 48 h, with hydrogen gas added after the first 24 h, increases the conversion to 87% (entry 4). Even though the conversions of these cyclic alkenes range from 33%–83% after 24 h, the selectivity remains excellent in all cases.

Next, the reactivity of isolated dienes with PdNP was investigated. In contrast to stilbene, a pentadiene system is not as sterically hindered while still having strong interaction with the PdNP surface. It was projected that symmetric 1,4-pentadiene (19) might first isomerize to conjugated 1,3-pentadiene (20), followed by hydrogenation of the terminal alkene, forming 2-pentene (2) (Scheme 1). Alternatively, it was also possible that 19 would be directly hydrogenated to 1-pentene without the intermediate 20, similar to 1,4-cyclohexadiene (13).

The reaction progress was followed with <sup>1</sup>H NMR spectroscopy (Fig. 1). The gradual decrease in the αCH<sub>2</sub> signals at ~2.8 ppm of 19 directly correlates to the consumption of 19.

Scheme 1 Possible pathways to 2.

Fig. 1 <sup>1</sup>H NMR of 19 conversion to 2 over time.

Since the characteristic vinyl proton signals at 6–7 ppm of 20 is not observed while the new characteristic αCH<sub>2</sub> signals at ~1.4 ppm of 1 is detected, the hydrogenation pathway must be the mechanism by which 2 forms. Therefore, we propose the mechanism (Fig. 2) of 1,4-pentadiene (19) isomerization and hydrogenation to 2-pentene (3) on thiolate-capped PdNP to be direct di-σ bond formation after substrate adsorption *via* two Pd-π bond formation. This allows two hydrogen atom insertions to occur simultaneously, resulting in the formation of 1 from the di-σ bonded intermediate A. With only a single alkene moiety, 1 can either desorb or isomerize to 2 *via* mono-σ bonded Pd-alkyl intermediate C. This is followed by β-hydride reductive elimination to form Pd-π bond intermediate D and 2 desorbs to create free space on the PdNP surface to restart the catalytic cycle.

Isolated dienes with αCH<sub>2</sub> such as 1,4-cyclohexadiene (13) and 1,4-pentadiene (19) were directly hydrogenated without initial isomerization while larger activated alkenes such as stilbenes (8 and 10) were much less reactive, with 10 preferring *cis*-to-*trans* isomerization over hydrogenation. It would therefore be interesting to examine the reactivity of alkenes with both an activating phenyl ring and αCH<sub>2</sub> (Table 4). *trans*-β-Methylstyrene (21) only underwent 10% conversion (entry 1) while allylbenzene (22) underwent 92% conversion (entry 2). This result confirms a low reactivity of di-substituted alkenes, especially *trans*-alkenes, for the catalytic reaction of deactivated PdNPs. The conversion of 1-phenyl-3-butene (23) was >99% with 96% selectivity for its isomerization products (entry 3), 1-phenyl-1-butene (25) and 1-phenyl-2-butene (26), with the selectivity of 13% and 87%, respectively.

The results showed that the proportion of isomers in the equilibrium mixture of alkenes depended largely on the structure of starting alkenes as indicated by the isomerization of 22 and 23 to the corresponding disubstituted alkenes. The ratio of *trans*/*cis* isomers for the reaction of 22 was 10.1, which was much greater than the *trans*/*cis* ratio for the reaction of 23 (the *trans*/*cis* ratio of 25 and 26 were 2.7 and 3.5, respectively). This indicated the location of phenyl group near β-H elimination site might decrease the activation energy for more thermodynamically stable *trans* products. The overall results prove that the deactivated PdNPs favor single isomerization of mono-substituted alkenes to *trans*-di-substituted alkenes. Despite the steric bulk of the benzene ring, the reactivity of

these 1-phenyl,  $\alpha$ -proton containing alkenes (**22** and **23**) on PdNP is comparable to the reactivity of terminal monoalkenes, such as 1-pentene (**1**) producing mostly isomerization products.

In general, acyclic alkenes hydrogenation or isomerization can be predicted (Scheme 2). Diene directly hydrogenates to monoene without isomerization; monoene's reactivity with PdNP depends on its structure. If it is mono-substituted with  $\alpha\text{CH}_2$  (**1**, **22**, **23**) or *cis* di-substituted (**10**), isomerization is favored. If it is both unactivated and too bulky (**4**) or *trans* di-substituted (**8**, **21**), low reactivity is predicted. If it is mono-

Scheme 2 Expected reactivity of alkenes on PdNP.

substituted but activated and does not contain  $\alpha\text{CH}_2$  (**6**), hydrogenation occurs.

To test these predictions, the reactivity of 1-phenyl-*trans*-1,3-butadiene (**24**) was examined. This is an interesting diene due to the presence of two activated alkenes capable of being hydrogenated. Based on the generalizations, **24** will undergo one hydrogenation event, forming **25** with small amounts of **23**. Mono-substituted **23** with  $\alpha\text{CH}_2$  will then isomerize to **26**, which can further isomerize to **25**. As a result, the monoene major product expected is di-substituted monoene **25**. Indeed, GC/MS analysis after 24 h reaction reveals that the reaction was 72% selective for **25**, with a *trans/cis* ratio of 4.2. Its isomer **26** was produced in 12% with a *trans/cis* ratio of 4.7 (Scheme 3). **24** underwent 15% conversion to the complete hydrogenation product **27** via both **25** (major) and **26** (minor) as intermediates. In comparison, **21** underwent only 8% conversion to its corresponding hydrogenation product. The increased hydrogenation activity for **24** compared to **21** can be accounted for by the better p orbital overlap of **24**, which allows it to be adsorbed closer to the surface of PdNP initially.

## Conclusions

We have taken advantage of the specific di- $\sigma$  bond that must form with Pd surface before hydrogenation takes place in higher alkenes. Thiolate ligands prevent sterically hindered

substrates from forming these di- $\sigma$  bonds unless the substrate has good p orbital overlap capable of forming multiple Pd- $\pi$  bond interactions. After a single hydrogenation in these substrates, only  $\pi$  interactions can be made with PdNP due to the loss of p orbital overlap, discouraging subsequent hydrogenation from occurring. Even though isomerization can still take place *via* mono- $\sigma$  bonded intermediates, this can be exploited in order to selectively synthesize di-substituted internal alkenes.
