Origins of observed reactivity and specificity in the addition of B₂Cl₄ and analogues to unsaturated compounds†

Cristina Pubill-Ulldemolins,^a Elena Fernández,^b Carles Bo*^a and John M. Brown*^c

In 1954 Schlesinger and co-workers observed the direct reaction of diboron tetrachloride with simple organic compounds under mild conditions, the 1,2 addition product being formed with either ethylene or acetylene. In the following 25 years a series of addition reactions to simple alkenes, alkynes and dienes was demonstrated. B₂F₄ was shown to react in similar manner, albeit under more forcing conditions. Crucially, it was demonstrated that the addition to (*E*)- or (*Z*)-but-2-ene occurred with *cis*-stereospecificity. Only sporadic interest was shown in this field thereafter until catalysed addition reactions of diboron reagents were realized. Encouraged by this revival of interest through the discovery of transition-metal and nucleophilic catalysis of diboryl additions, DFT analysis of uncatalysed additions of B₂X₄ has been carried out and interpreted. This includes the relative reactivity of several B–B reagents with ethene, and that of B₂Cl₄ vs. B₂F₄ additions, including benzene, naphthalene and C₆₀ as reactants. This allows the analysis of relative reactivity *vis-à-vis* substitution on boron, and also direct comparison with hydroboration by HBCl₂. [4 + 2] Addition of diboron reagents to dienes with B–B cleavage competes with direct [2 + 2] addition, favourably so for B₂F₄. The computational results demonstrate that the stereospecific addition to isomeric but-2-enes is a rare concerted [2σ_s + 2π_s] process.

Introduction

The first addition of a boron reagent to an alkene was conducted by Schlesinger *et al.* in 1954,^{1a} three years before H.C. Brown's seminal papers on hydroboration.² In that first paper, a 1 : 1 adduct formed at –80 °C between ethene and B₂Cl₄ **1** was demonstrated, along with related products formed by addition of B₂Cl₄ to ethyne or cyclopropane, the latter occurring only at 0 °C. In their later full paper, addition of the boron reagent to a wide range of alkenes was carried out, including double addition to butadiene.^{1b} The addition chemistry of B₂F₄ **2** was similar but required much more forcing conditions. In other early work the stabilization of the reagent **1** by trichloroethene for addition reactions was noted, and reaction with both *cis*- and *trans*-but-2-ene observed although the stereochemical course could not be settled.³ For ethyne,

cis-addition of **1** was defined, and later extended to higher alkynes.⁴ Slow reaction was observed with aromatic compounds, leading to a single electrophilic substitution product C₆H₅BCl₂ from benzene, whilst a double addition product was obtained from naphthalene causing saturation of one ring.⁵ Progress was limited in these early papers by the instability and limited availability of B₂Cl₄, produced by an electric discharge through BCl₃ at low temperatures.⁶ Later on, B₂Cl₄ became available on a 10 g. scale employing Cu and BCl₃ in metal-vapour deposition.⁷ To this day more convenient syntheses of the reagent are lacking, although a simple route to its bis-dimethylamine adduct is known.⁸ Further work will be stimulated by the application of **1** in semiconductor doping.⁹ The analogous compound B₂Br₄ **8** also adds easily across the double bond of alkenes,¹⁰ and is more readily accessible, encouraging a reappraisal of its reactivity.¹¹ In summary, the concerted uncatalyzed addition of two heavy atoms from B₂X₄ to C–C unsaturation remains a rare and intriguing reaction type. The interest of these addition reactions for synthetic chemists was substantially enhanced when it was shown by oxidation and characterization of the ensuing chiral diols that the addition of B₂Cl₄ to isomeric butenes was *cis*-specific (Scheme 1).¹² Addition of the reagent to cycloalkenes was likewise shown to be *cis*; with cyclohexa-1,3-diene, two sequential *cis*-specific additions occur on opposite faces.¹³ Selectivity in

the addition of to the double bonds of methylenecyclopropane or vinylcyclopropane over competing C–C cleavage pathways was demonstrated.¹⁴ Further work showed that the addition of reagents **1** or **2** to buta-1,3-diene gave a 1 : 1 product that was assigned to 1,4-addition based on NMR spectra.¹⁵ After that, brief summaries appeared in a broader review of boron halide chemistry,¹⁶ otherwise the topic has been neglected, revived through the important discoveries of catalysed additions of diboryl compounds to alkenes and alkynes described below.

Compared to diboron dihalide species, boron derivatives which contain B–O or B–N bonds are more stable and less reactive as a consequence of the π donation from the lone pair of O and N substituents to the empty p_z boron orbital.¹⁷ The lowered reactivity laid the foundations for catalytic addition; Miyaura and co-workers utilised a Pt[0] complex to activate tetraalkoxydiborons and thus catalysed *cis*-1,2-diboron addition to unsaturated substrates.^{18a} This was subsequently extended to alkene additions,^{18b} and further to catalytic asymmetric synthesis.^{18c} Catalytic diboration has been extended to other metals and even demonstrated with Au nanoparticles,¹⁹ but not all such catalysts necessarily activate the diboron reagent by oxidative addition (Scheme 2a).²⁰ Instead σ -bond metathesis between the metal entity and diboron reagent was suggested to play a key role (Scheme 2b).²¹ Although tetraalkoxydiborons are inactive under mild conditions for the diboration of unsaturated compounds, they can be catalytically activated by the addition of a Lewis base (A).²² A reactive Lewis acid–base adduct $[A \rightarrow B(OR)_2-B(OR)_2]$ can be formed under these conditions which facilitates the transfer of a boryl moiety with enhanced nucleophilic character (Scheme 2c). For

reaction with electrophilic alkenes, the Lewis base may be a stable carbene,^{22b} or a chiral phosphine capable of inducing product asymmetry.^{22c} In the latter case a phosphonium cation formed by reaction of phosphine and electrophilic alkene forms an ion-pair with the reacting borate.^{22d} Remarkably, addition to unactivated alkenes has been accomplished with catalytic methoxide/MeOH as Lewis base.²³ Finally, we note that activation of modified dihalodiboranes $Ar_2X_2B_2$ with a range of phosphine and N-heterocyclic carbenes reveals a rich chemistry that has just begun to be explored.²⁴

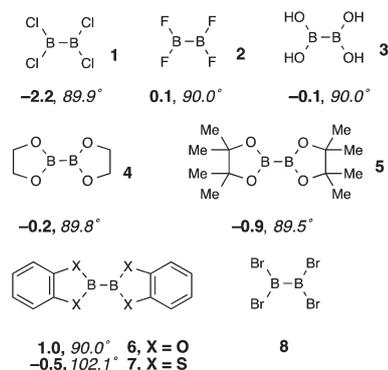

Significant questions remained unanswered with regard to the original addition reaction – *e.g.* why is such high reactivity observed with B_2Cl_4 , and why is the reaction with 1,2-disubstituted alkenes stereospecific?

Results and discussion

Relative reactivity of various B–B compounds towards ethylene

The molecular structure of B_2Cl_4 is known both in the gas phase and in the solid state. IR/Raman and electron diffraction analyses confirm D_{2d} symmetry,²⁵ with a rotational barrier <2 kcal mol⁻¹; in the crystalline state the molecule is planar, however.²⁶ For B_2F_4 , the planar form is marginally preferred over the orthogonal form.²⁷ The CSD X-ray database contains *ca.* 100 B_2X_4 (X = N, O, S, Hal) structures, for which non-planar entities close to the orthogonal structure predominate over near-planar geometries. Notable exceptions lie in cases where $X_4 = O_4$, for which the planar form is generally preferred in the crystal state.²⁸

Our initial DFT calculations conformed well with these observations (Scheme 3), finding two stationary states with fairly closely matched energies in all cases except B_2Cl_4 **1**, one corresponding to the planar form, and the other closer to the orthogonal D_{2d} form. In the exploratory phase of the work, three different functionals (B3LYP, M06-2x and ω B97X-D),^{29–31} were employed, with comparable results insofar as the ground-

Scheme 3 DFT computed B_2X_4 initial states. Electronic energies relative to the planar conformer (ω B97X-D, 6-311G(d,p), gas phase, ZPE corrected) and X–B–B–X dihedral angles for the orthogonal isomer are shown. For **8**, only the latter was found. The ESI† also shows results with other functionals.

state structure and relative energies of the two conformers of the B_2Cl_4 reagent were concerned. The planar form was marginally the more stable one in the case of B_2F_4 **2**, and significantly so for the catechol derivative; only in the thiocatechol case did the X–B–B–X dihedral angle deviate far from 90° in the nonplanar form. The relevant observations are in accord with previous spectroscopic and computational work on the tetrahalodiboranes (ref. 25–27).

The choice of the DFT functional became more critical when considering the reactions of diboranes with alkenes. According to Urry and Schlesinger's original paper,^{1a} the initial addition of B_2Cl_4 **1** to C_2H_4 occurred to a very significant extent in 4 h. at $-80^\circ C$; the half-life at this temperature then translates to a Gibbs free energy value, $\Delta G^\ddagger = 16.9$ kcal mol⁻¹. Comparable reaction with B_2F_4 **2** only occurred at higher temperatures. Other addition reactions of B_2Cl_4 from different research groups were conducted in diverse ways; between $-80^\circ C$ and $20^\circ C$, neat, in solvent or in the vapour phase. For this reason all the computed results in the paper arise from the zero-point corrected electronic energy, in order to provide a basis for comparison that avoids the complications of varying $T\Delta S$ and solvent effects. Given the lack of quantitative experimental data for comparison, comparisons of relative rather than absolute energy are needed. Reaction between C_2H_4 and **1** was examined by using several commonly used DFT functional: the ZPE-corrected transition state energy for 1,2-addition being 22.8 kcal mol⁻¹ ($\Delta G_0^\ddagger = 35.3$ kcal mol⁻¹) above the isolated reactants using B3LYP as functional and the 6-311G(d,p) basis set,^{29a} reduced to 15.6 kcal mol⁻¹ ($\Delta G_0^\ddagger = 27.6$ kcal mol⁻¹) when D3-dispersion was included.^{29b} Using the Truhlar functional M06-2X,³⁰ a much lower value of 7.4 kcal mol⁻¹ was obtained ($\Delta G_0^\ddagger = 19.6$ kcal mol⁻¹), whilst applying the ω B97X-D functional gave a value of 12.0 kcal mol⁻¹ ($\Delta G_0^\ddagger = 23.7$ kcal mol⁻¹).³¹ It was decided that the last-named functional would be the most suitable for general analysis of B_2X_4 addition chemistry, and the body of results described here were obtained using this throughout, together with the 6-311G(d,p) basis set. At this stage we compared the reactivity of different B_2X_4 reagents towards C_2H_4 shown in Fig. 1; only the halo-compounds (X = F, Cl) had been applied in alkene additions before, and the fluoride is the less reactive of the two.^{1b} When dispersion corrections were included in the functional an energetically favourable van der Waals (vdW) complex between the halodiborane or hydroxydiborane reactants and C_2H_4 was located as a separate stationary state for **1**–**3**, although not for **4**–**7**. Stabilization energies E for these vdW complexes varied between 3.8 and 5.5 kcal mol⁻¹.

For the diboron tetrahalides **1**, **2** and **8** the four atoms involved in bond making and breaking are close to coplanar in the transition-state; the same is true for other examples. The structure of the transition states shows one near-tetrahedral boron atom B with advanced bonding to both carbons, the second one B' less strongly involved and closer to its original trigonal geometry. The leading boron exhibits a BCC angle close to 70° at the transition state, conserved throughout the series. This resembles the analogous TS for simple hydrobora-

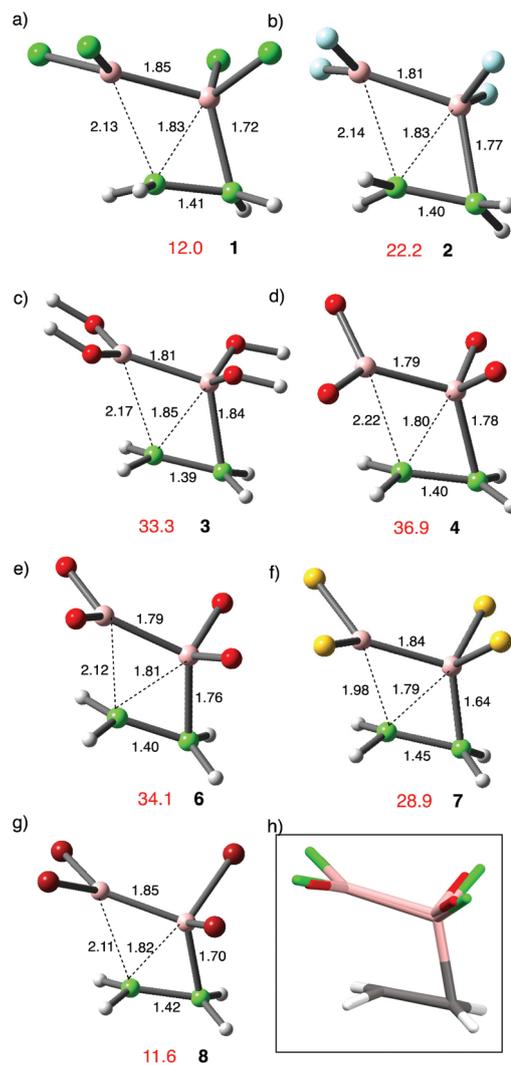

Fig. 1 (a)–(g) Transition-state structures for the addition of borane reagents to ethane with energies in red (kcal mol⁻¹) relative to the isolated reactants and numbering as in Scheme 3; structures **4**, **6** and **7** are drawn truncated. (h) shows superimposition of transition states for **1** and **3**, DFT level as Scheme 3.

tions, derived in published computations,³² and this encouraged comparison of our results for B_2Cl_4 with those for hydroboration by $HBCl_2$ (*vide infra*). The spread of transition-state energies is substantial, demonstrating high sensitivity of B–B bond activation to the substituents on boron. On this basis, the experimentally observed unreactivity of di-oxoboron reagents in addition to alkenes under non-catalytic conditions is corroborated, although a lower barrier for the sulfur analogue (Fig. 1f vs. 1e) is clearly predicted.

Analysis of the IRC's for the pathway with both **1** and **2** in their reaction with ethene (Fig. 2) demonstrates that the coplanar alignment of reactants ($B'BCC' = 0^\circ$) observed at the transition state is already present in the early phase of reaction, and persists right through to an initially B–C–C–B eclipsed product geometry. The coplanarity of the reacting atoms also

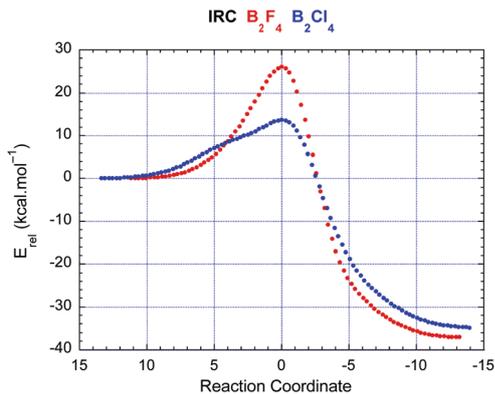

Fig. 2 IRC traces for **1** (blue) and **2** (red) reacting with ethene according to Fig. 1.

suggests that vdW complexes are not directly involved on the reacting pathway, since these complexes possess C_2 symmetry with pronounced twisting between the two components.

The most obvious factor favouring addition to ethylene of B_2Cl_4 **1** or B_2Br_4 **8** over the related reactions of B_2F_4 and $B_2(OR)_4$ is the later transition states for **1** and **8**. Compared to the other examples, they exhibit longer B–B and C=C bonds and a shorter C–B bond. The energy differences involved are substantial although the geometric changes are very subtle, as witness the superimposed transition states from **1** and **4** shown in Fig. 1h. The observed variations in activation energy do not follow trends in BDE's,³³ or B–B bond lengths, which do not vary much.³⁴ Hence other possible reasons need to be considered. The energy differences observed for the simple reagents correlate with the value of the ^{11}B – ^{11}B *sym*-stretching frequency, derived from computed Raman spectra of the D_{2h} isomers using the same conditions as Fig. 1. For B_2Cl_4 this is observed at a frequency of 1111 cm^{-1} and for B_2Br_4 **8** at 1102 cm^{-1} (D_{2d} isomer) but for the less reactive B_2F_4 and $B_2(OH)_4$ at frequencies of 1395 cm^{-1} and 1423 cm^{-1} respectively. For diboryls **6** and **7** the B–B stretch is split through coupling to *sym*- and *asym*-aromatic C–C stretching modes, and this complicates detailed analysis, although the same trend is observed, since the sulfur-substituted diboryl $B_2(\text{Scat})_2$ **7** possesses an activation energy for addition to ethene 5.2 kcal mol^{-1} lower than its oxo-analogue **6**. In accord with this, the ^{11}B – ^{11}B stretching frequencies in the computed Raman spectra of **7** are at $1131, 1177\text{ cm}^{-1}$ for $B_2\text{Scat}_2$ **7** and $1377, 1449\text{ cm}^{-1}$ for $B_2\text{Cat}_2$ **6**. The softer symmetrical B–B stretching vibration in **1**, **7** and **8** is also associated with later transition states compared with **2**, **3**, **4** and **6**, as witness the shorter C–B and longer B–B' bond lengths seen in Fig. 1. Both boron atoms are re-hybridized towards sp^3 at the transition states, less so for **7** (see ESI† pp. 83 and 84).

Relative reactivity of substituted alkenes towards B_2Cl_4

These results encouraged analysis of addition reactions with B_2Cl_4 **1**. For ethyne, a vdW complex with the reagent was

^a Calculations were carried out using Gaussian09 rev D1, with the ω B97x-D functional and 6-311G(d,p) basis set; ZPE corrected. ^b *prim*, *sec* and *tert*-refer to the more strongly B-bonded carbon at the TS. ^c ZPE-corrected energies in kcal mol^{-1} . ^d B_2F_4 **2** as reagent. ^e $HBCl_2$ **9** as reagent. ^f The isomeric vdW complex was not found.

located with the partners orthogonal to one another; the *cis*-1,2-addition to ethyne was comparable in energy to that of ethene. Exploring the series of simple alkylethenes showed modest changes in TS energy with increasing methylation, and likewise to increasing stability of vdW complexes. For propene and 2-methylbut-2-ene, two isomeric pathways were located depending on which sp^2 -carbon had the shorter B–C bond at the TS. Tetramethylethylene did not permit location of either vdW or TS states. The energy of the *gauche*-product was also computed, and revealed the destabilizing effects of additional methylation. The comparison between **1** and **2** was extended to propene. B_2F_4 formed stronger vdW complexes and also showed transition state energy barriers $\geq 10\text{ kcal mol}^{-1}$ higher (Table 1, entry 5). The comparative reactivity of **1** and the hydroborating agent $HBCl_2$ **9** was also computed for the range of substrates.

Hydroboration of alkenes by BH_3 decreases in reactivity with increasing alkyl substitution of the substrate,³⁵ in contrast to conventional electrophilic additions.³⁶ Results from the present calculations for B_2Cl_4 addition do not fit either pattern, the activation energy being comparable for propene and the but-2-ene isomers (entries 3, 6 and 7; Table 1), but all lower than for ethene or ethyne (entries 1 and 2). Only for the disfavoured pathway with propene and both pathways for trimethylethylene (TME) is there a significant increase in activation energy *vs.* ethene (entries 4, 8 and 9). For unsymmetrical alkenes, it is favourable to form the *prim*-C–B bond in propene first, but by contrast the *tert*-C–B bond in trimethylethylene (TME) first; compare entries 3,4 and entries 8,9.

The TS dipole moment in additions of **1** is 4.6 D for ethene and increases only marginally with increasing substitution to 5.2 D for 2-methylbutene, implying significant polar character throughout, as in electrophilic addition. (*Z*)-Butene shows higher affinity for vdW complexation with **1** than (*E*)-butene, but is the less reactive (entries 6 and 7). In entry 10, *cis*-

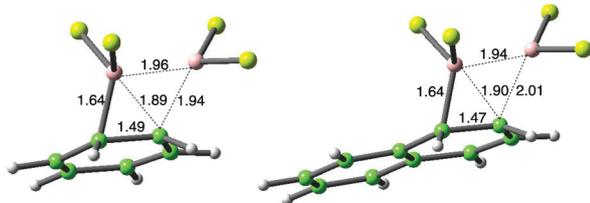

Fig. 3 Comparison of TS structures for addition of B_2Cl_4 to benzene and naphthalene; distances in Å.

addition of B_2Cl_4 to naphthalene occurs through an energetically accessible and exergonic pathway, in accord with the original experiments.⁵ This contrasts with the higher energy seen in addition to benzene (entry 11) where monosubstitution rather than addition had been observed experimentally. Addition to benzene is only very weakly exergonic, encouraging reversibility. In both cases a strong vdW interaction between the reactants was observed, with the B–B bond centrally aligned over the arene (Fig. 3); see ESI† for details.

Dichloroborane has occasionally been employed as a hydroborating reagent. Aside from a series of observations in hexane solvent, mainly using fluoroalkene reactants, relatively slow rates have been reported for this addition reaction.³⁷ This is a consequence of strong donor complexes to solvent when reaction is carried out in THF or ether; the reactions are faster in hydrocarbon media. Table 1 summarizes the results of a parallel set of calculations carried out on addition of $HBCl_2$ **9** to alkenes. For each case a vdW complex was located (two in the case of propene) rather less favourable than the corresponding complexes from **1**. The transition states were readily defined, and the *anti*-Markovnikov pathway is strongly preferred (entries 3 vs. 4; 8 vs. 9).³⁸ There is a broad correspondence between the two addition reactions, with the TS for hydroboration 3–5 kcal mol⁻¹ lower in energy than the TS for diboration. Entry 8 is an exception, for which addition of **9** to trimethylethylene (TME) is particularly favourable relative to the addition of **1**. The transition state structures for both pairs of regioisomeric pathways in addition to TME (entries 8 and 9) are shown in Fig. 4.

In these examples steric effects involving BCl_2 and the tertiary CMe_2 moiety are manifested at their transition states in different ways. For the *sec*-pathway with **1** shown in (a), there is a short B–C bond at 1.62 Å, but the BCC' angle is widened to 78° from the ideal 70° found with ethene. For the *tert*-pathway shown in (b) a torsional twist of B'BCC' to 20° reduces the steric clash between B'Cl₂ and CMe_2 . This steric clash is absent in (c) but present again in (d) and contributes to their 5.5 kcal mol⁻¹ difference in TS energy. The *sec*-pathway possesses the shorter leading B–C bond at 1.70 Å vs. 1.76 Å. The influence of steric effects on reactivity was reinforced by a failure to find a transition state structure for addition of B_2Cl_4 to tetramethylethylene.

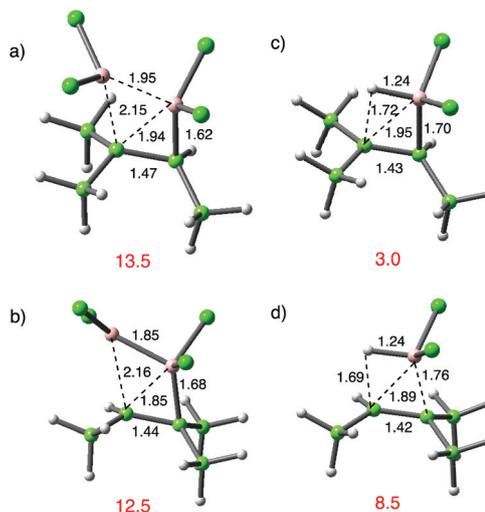

Fig. 4 Comparative geometries for trimethylethylene reacting with **1** (a,b) or **9** (c,d). The upper structures show advanced boron bonding to the secondary-carbon, and the lower structures to the tertiary-carbon. Distances are in Å, TS energies in kcal mol⁻¹ relative to the reactants; ωB97x-D/6-311G(d,p).

Polarity effects on reactivity

The trends observed for reactivity in B_2Cl_4 addition vs. methyl substitution suggested that the alkene has nucleophilic character at the transition-state, consistent with the higher dipole moments observed for the transition states compared to either reactants or products. To test this, the reaction of (*E*)-butene was repeated in solvent of varying polarity using the polarized continuum model (PCM). The results showed a clear trend; the energy is lower in heptane ($\epsilon = 1.92$) than in the gas phase, further lowered in THF ($\epsilon = 7.58$) and further still in CH_3CN ($\epsilon = 37.5$). The overall range of energies is 3.02 kcal mol⁻¹ so that the positive influence of increased solvent polarity is substantial (Fig. 5).

The results in Table 1 also make the prediction that an electrophilic alkene would show lower reactivity towards B_2Cl_4 . Catalysed additions are well known in this sphere and gener-

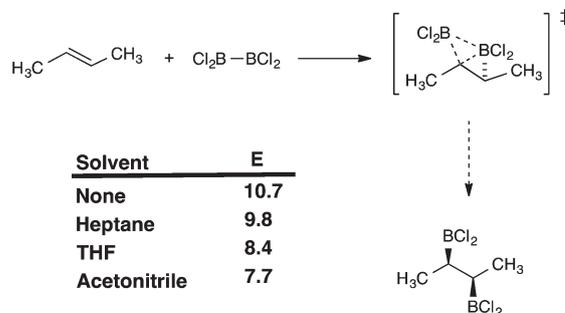

Fig. 5 Solvent effects on the ZPE-corrected electronic TS energy of addition of B_2Cl_4 to (*E*)-butene; ωB97x-D/6-311G(d,p); PCM with SCRF model; values in kcal mol⁻¹.

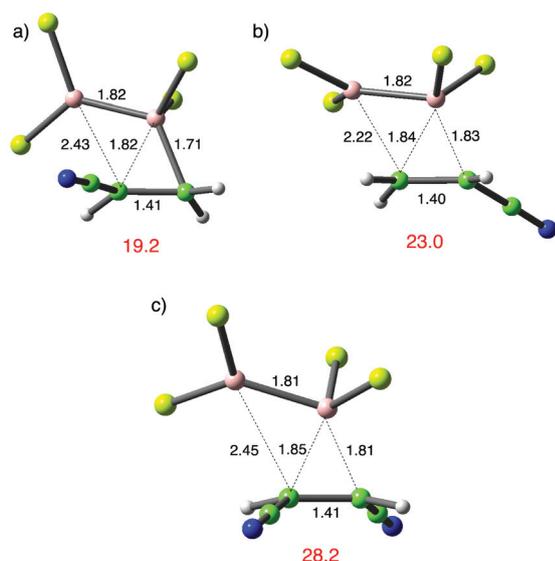

Fig. 6 Comparative geometries for the addition of B_2Cl_4 to electrophilic alkenes; (a) acrylonitrile, favoured regioisomer; (b) acrylonitrile, disfavoured regioisomer; (c) (*E*)-butene. ZPE-corrected TS electronic energies in kcal mol^{-1} ; $\omega B97x-D/6-311G(d,p)$.

ally lead to β -boration; with $\alpha\beta$ -unsaturated carbonyl compounds this most likely arises through direct 1,4 addition. This is less likely, albeit still possible with unsaturated nitriles and hence the simple compounds acrylonitrile and (*E*)-dicyanoethene were selected.³⁹ The computational results confirm that their reaction with B_2Cl_4 is less favourable than the typical examples in Table 1, as shown in Fig. 6. The much higher TS energies observed compared to typical B_2Cl_4 additions to alkenes in Table 1 are associated with distinct TS geometries. In the favoured case (a), the leading bond length from B is comparable to the alkene examples but the less developed bond from B' is much longer. For the unfavourable addition in (b) it is the leading bond from B to the nitrile bound carbon that is anomalously long. For (*E*)-dicyanoethene in (c) both bonds are longer at the TS. When the less developed bond from B' is to a cyano-substituted atom, that Cl_2B' group is twisted to minimize contact with the cyano-group. These results reaffirm preferred nucleophilic character in the alkene to facilitate reaction.

Reactivity of fullerene C_{60} towards B_2Cl_4

Covalent derivatives of C_{60} and other carbon allotropes are of interest in many applications and especially in the rapidly growing field of bioconjugates.⁴⁰ This requires functionality in the fullerene, and at present there is a limited range of organic reactions that work well, and even fewer that involve controlled monoaddition.⁴¹ Indirect alkynyl group substitution is feasible, however and provides a route to 'Click' coupling chemistry.⁴² Hydroboration of fullerenes occurs, but leads only to isolation of di- and polyhydrides, or to products of further oxidation.⁴³ An ability to form acid-stable C–B bonds to fullerenes

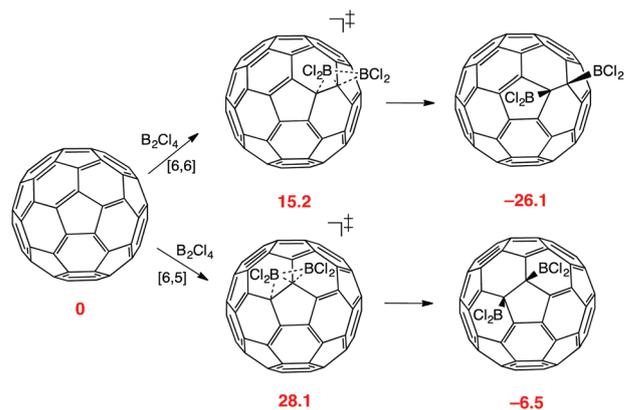

Fig. 7 The favoured [6,6] and disfavoured [6,5] pathways for addition of B_2Cl_4 to C_{60} . The quoted values of ZPE-corrected electronic energy are from DFT calculations with the $\omega B97-xD$ functional and 6-31G(d,p) basis set.

in isolable intermediates is hence an attractive prospect since this opens new routes to their catalytic cross-coupling chemistry. Given the ease of addition of B_2Cl_4 1 to alkenes and to naphthalene, we wondered whether an addition product with C_{60} would be energetically accessible likewise.

In any 1,2-addition to C_{60} , there are two possible pathways depending on whether reaction occurs to the bond at a [6,6], or [6,5] ring junction. The latter involves a more drastic break in conjugation and is disfavoured.⁴⁴ A stable vdW complex between C_{60} and B_2Cl_4 was found, $7.1 \text{ kcal mol}^{-1}$ more stable than the isolated reactants. The transition state for the addition of B_2Cl_4 to the preferred [6,6] junction was readily located, with a calculated energy of $15.2 \text{ kcal mol}^{-1}$ (Fig. 7). The alternative addition of B_2Cl_4 to the [6,5] ring junction involved a far higher energy transition state, and a product that is $19.5 \text{ kcal mol}^{-1}$ less stable. Overall, these results endorse the established principle that reagents engaging by initial 1,2 addition exert a strong preference for the [6,6]-junction, observed through both reactivity and product stability.⁴⁵ This accords with the relative energies of the related $C_{60}H_2$ isomers using the same DFT functional and basis set.⁴⁶

1,2 vs. 1,4 addition possibilities; relative reactivity

B_2F_4 vs. B_2Cl_4

Alongside the several reports of 1,2-additions of B_2X_4 additions to alkenes there is a single report of 1,4-addition to buta-1,3-diene.¹⁵ This encouraged a broader analysis of the addition chemistry of dienes, and the results are shown in Fig. 8 below. Reactions of both B_2Cl_4 and B_2F_4 were analysed.

With buta-1,3-diene and B_2Cl_4 , low energy 1,2-addition pathways were discovered for both the *s-cis* and *s-trans* conformations; this latter pathway was verified for B_2F_4 2. Attempts to find a normal 1,4-addition pathway from the *s-cis* isomers were not successful; the reaction course diverted to 1,2-addition. There is the intriguing suggestion in an early paper that the *s-cis* conformation might participate in a

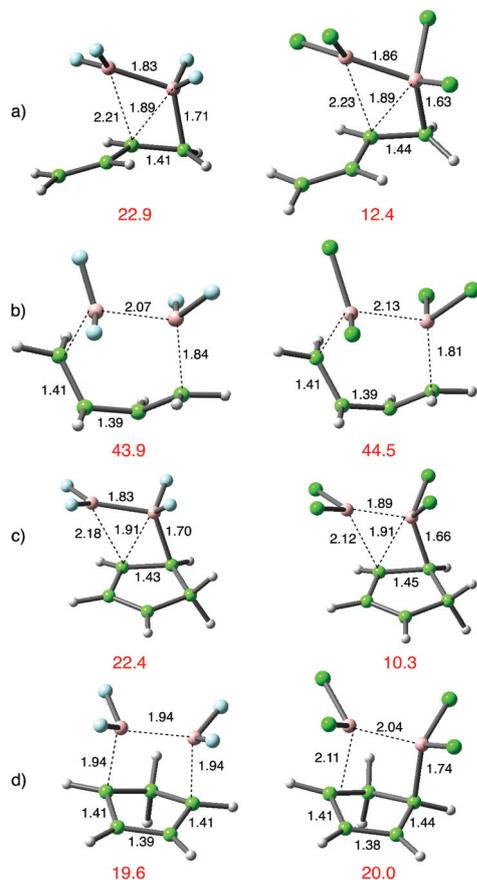

Fig. 8 Transition-state structures for 1,2- or 1,4-addition to dienes, comparing B_2F_4 **2** with B_2Cl_4 **1**; (a) 1,2-addition to *s-trans*-but-1,3-diene; (b) the high energy 1,4-addition pathway; (c) 1,2-addition to cyclopentadiene and (d) 1,4 addition to cyclopentadiene. DFT as in Scheme 3.

symmetry allowed [$4\pi_a + 2\sigma_a$] cycloaddition,¹⁵ with orthogonal approach of the diboron reagent to the diene. We were unsuccessful in attempts to locate a transition state for this pathway, but the corresponding *s-trans* conformation proved more fruitful. A nicely symmetrical, albeit comparably high energy [$4\pi_s + 2\sigma_s$] transition state was found for both B_2Cl_4 and B_2F_4 giving rise to the symmetrically 1,4-disubstituted (*E*)-but-2-ene.

With cyclopentadiene, both 1,2 and 1,4 addition pathways were located with B_2Cl_4 , and the 1,2-addition shown in Fig. 5(c) was energetically favoured by *ca.* 10 kcal mol⁻¹ over the same pathway for B_2F_4 and by a similar amount over the corresponding 1,4-addition shown in Fig. 5d). In contrast, the 1,4-addition pathway to cyclopentadiene with B_2F_4 was favoured over 1,2-addition, and was even lower in energy than the corresponding 1,4-addition with B_2Cl_4 . Furthermore, the transition state (d) arising from B_2F_4 addition was symmetrical with both C–B bonds equal at 1.94 Å, whilst the TS from B_2Cl_4 lacked symmetry, with one C–B bond more advanced than the other, at 1.74 Å vs. 2.11 Å. The contrasting transition-state

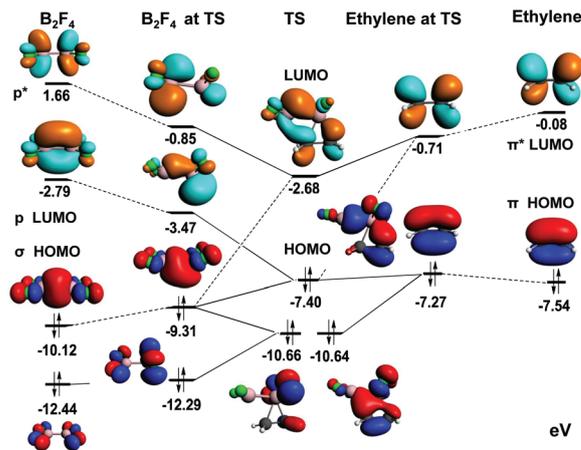

Fig. 9 Orbital analysis of the reaction pathway for addition of B_2F_4 to C_2H_4 .

structures of the 1,2 and 1,4-addition routes for reaction of B_2F_4 with C_4H_6 and C_5H_6 are shown in Fig. 5(c) and (d).

Basis for the stereoselective pathway with but-2-enes

Experimental verification of the stereospecific addition of B_2Cl_4 to butenes by Rudolph and by Zeldin *et al.*,¹² for a reaction that is (formally at least) a symmetry-forbidden $2\pi_s + 2\sigma_s$ process requires further analysis. The frontier MO's were analysed at the B3LYP level as demonstrated in Fig. 9, and reveal the basis for a concerted, stereospecific reaction as is observed. This figure shows bonding orbitals of the reactants that are closely involved in generating the three highest energy orbitals of the TS, and the critical role of low-lying antibonding orbitals. Bonding between the proximal boron and its carbon is seen in $TS_{(HOMO)}$ and between the distal boron and its carbon in $TS_{(HOMO-1)}$. This requires a complex interplay between bonding and nonbonding orbitals of the reactants that is revealed by the TS fragment analysis shown. $B_2F_4(LUMO)$ mixes strongly with the symmetry-matched $C_2H_4(HOMO)$, and this makes the main contribution to $TS_{(HOMO)}$. The weaker involvement of $B_2F_4(LUMO+1)$ leads to the less prominent distal bonding expressed in $TS_{(HOMO-1)}$. Overall, the combination of orbital interactions between B_2F_4 and the alkene permits a formally symmetry forbidden process to occur in a stereospecific manner. Orbital analysis of the TS for reaction between B_2Cl_4 and C_2H_4 is entirely comparable, save additional Cl-localised orbitals of comparable energy to (HOMO–1).

Computational details

In the early phase of the work geometries and analytical vibrational frequencies were computed at the B3LYP//6-311g-(d,p) level *in vacuo*. The results obtained for addition of B_2Cl_4 to C_2H_4 were compared with calculations using functionals that included explicit treatment of dispersion energy, M06-2X, ω B97x-D and B3LYP-D3 (ref. 25–27). All of these were available within Gaussian09.⁴⁷ (Rev. D-01). The choice for all further

work was ω B97x-D, based on the reasonable values of activation energy obtained when compared to available experimental. ZPE-corrected electronic energies are normally reported; for the solvent effect data shown in Fig. 5, IEFPCM (Integral Equation Formalism of the Polarized Continuum Model) was employed. All transition states reported here possessed a single imaginary frequency of $\geq 300 \text{ cm}^{-1}$.

Summary and conclusions

This work was initially driven by the longstanding observation of stereoselectivity in the reaction between B_2Cl_4 and 1,2-disubstituted alkenes. The literature on B_2Cl_4 chemistry contains a number of interesting but scattered observations that provided the stimulus for a broader overview of its addition chemistry. Work in this area ceased thirty years ago, partly because of difficulties in accessibility of the reagent, but also because of its instability towards disproportionation to BCl_3 and chloroboron clusters. Given the high level of current interest in catalytic additions of otherwise unreactive diboron compounds to unsaturated C–C bonds, this paper provides a set of benchmarks.

The calculations herein confirm that the simple addition of B_2Cl_4 to alkenes uncatalysed by artefacts (e.g. HCl) is feasible, and of lower energy than all comparable B_2X_4 additions save B_2Br_4 . Several novel observations arise from the current work. There is a robust transition state structure that operates across the B_2X_4 series studied and the reactivity in ethene addition correlates with the B–B *sym*-stretching vibrational frequency of the reagent. With increasing Me-substitution of the alkene, the polar character of B_2Cl_4 as electrophile initially reduces transition state energy, countered by increased steric effects with higher Me-substitution. Similar, but more pronounced trends are seen in a parallel analysis of HBCl_2 addition. The ease of reaction extends to 1,4-addition of B_2X_4 to dienes, this being the preferred reaction with B_2F_4 and cyclopentadiene. Only transition states for 1,2-addition were located with *s-cis*-buta-1,3-diene although an unprecedented higher energy 1,4-*trans*-addition could be located for the *s-trans*-isomer using either B_2Cl_4 or B_2F_4 . With cyclopentadiene, both 1,2 and 1,4 transition states were located. For B_2Cl_4 , the 1,2-pathway is lower in energy. The reverse is true for B_2F_4 , and in this case the 1,4 addition pathway is more favourable than for B_2Cl_4 . The transition state for B_2F_4 addition retains σ -symmetry, whilst for B_2Cl_4 it is unsymmetrical. The asynchronous concerted pathway observed here for 1,4 addition of B_2Cl_4 contrasts with Diels–Alder addition of symmetrical dienophiles to cyclopentadiene, where symmetrical transition-states along a synchronous pathway are generally preferred.⁴⁸

Given the range and ease of addition of B_2Cl_4 to unsaturated molecules found here, the topic merits experimental revival and extension. Easier access to diboron tetrahalides using modern synthetic methodologies would provide a crucial breakthrough. In particular, the easy addition reactions to naphthalene or C_{60} suggest a useful and mild method for

the functionalization of aromatic carbon frameworks and assemblies in Materials Science. More generally, the reagents are shown to be electrophilic in their addition chemistry, permitting insight into their appropriate application. The concerted uncatalyzed addition of two heavy atoms to C–C unsaturation remains a rare and intriguing reaction type.
