A systematic investigation of the influence of substitution at positions C-2 and C-3 on the azulene skeleton, based on NMR characterisation, is discussed with particular focus on the impact of the steric and electronic characteristics of substituents on the position of the norcaradiene–cycloheptatriene (NCD–CHT) equilibrium. Variable temperature (VT) NMR studies, undertaken to enable the resolution of signals for the equilibrating valence tautomers revealed, in addition, interesting shifts in the equilibrium.

Introduction

The addition of carbenes derived from α -diazocarbonyl compounds to benzenes, resulting in ring expansion to provide cycloheptatrienes, originally developed by Buchner at the end of the 19th century, is among the most synthetically powerful methods of transforming stable aromatic rings to much more reactive systems.^{1,2} Mechanistically, it is believed that this ring expansion occurs *via* initial carbene addition to provide a norcaradiene **1N** followed by reversible 6π electrocyclic ring-opening to the more stable cycloheptatriene tautomer **1T** with the equilibrium generally favouring the latter (Scheme 1).³ While the earlier studies were conducted either thermally or photochemically, this transformation became practically useful from a synthetic perspective with the advent of rhodium carboxylate catalysts in the 1980s.^{4–8}

Subsequent to the original work of Buchner, the existence of the norcaradiene tautomer was a topic of much dispute that was ultimately resolved in 1950s.³ The existence of the norcaradiene tautomer has also been irrefutably confirmed through trapping of this species in cycloaddition reactions and struc-

Scheme 1 Reaction of ethyl diazoacetate with benzene resulting in cycloheptatriene.

tural characterisation of the cycloadducts, for example by Vogel,⁹ Manitto¹⁰ and Doyle.¹¹ With the advent of NMR spectroscopy, a greater understanding of the norcaradiene–cycloheptatriene equilibrium emerged through direct observation of the interconverting species rather than inferring their existence by trapping experiments. In 1955, E. J. Corey first described the use of NMR spectroscopy in an attempt to study **2N** and **2T**, the enol acetate tautomers of the natural product eucarvone confirming only the presence of the cycloheptatriene structure (Fig. 1).¹²

Subsequent reports by Anet,¹³ Jensen and Smith,¹⁴ and Roberts¹⁵ further investigated the spectroscopic evidence for the detection of the elusive norcaradiene **3N** by VT-¹H NMR spectroscopy (Fig. 2). Even at temperatures as low as –150 °C, no signals for the norcaradiene were observed, however Rubin did succeed in directly observing the norcaradiene **3N** at low temperature (77 K) using UV, which allowed him to provide an insight into the kinetics of its interconversion to **3T**.¹⁶ Günther used low temperature NMR spectroscopy to confirm the existence of 'Buchner's acid' (Fig. 2) as a fluxional system, with only 3% NCD observed at low temperature (¹³C NMR at

–132.5 °C and ¹H NMR at –150 °C).¹⁷ Okamoto has described extensive variable-temperature NMR work in the study of the position of the norcaradiene–cycloheptatriene equilibrium of various substituted cycloheptatrienes.¹⁸

Hannemann has reported that the chemical shifts of the 1,6 H and C atoms of pure cycloheptatriene 3N lie in the region δ_{H} 5.2–5.3 and δ_{C} 120–130 respectively, whereas the corresponding signals in typical norcaradienes 3T resonate at δ_{H} 2.8–3.5 and δ_{C} 35–45.¹⁹ This tautomeric system is influenced by the steric and electronic effects of the substituents on the azulene framework. In general, the cycloheptatriene (CHT) tautomer is thermodynamically more stable than the norcaradiene (NCD) tautomer, which has a strained cyclopropane ring. Thus, the equilibrium lies on the side of the cycloheptatriene species (Table 1, entry 1). However, introduction of substituents on the norcaradiene framework has a dramatic effect on the relative stability of the two tautomers, through a combination of electronic and conjugative effects. Electron withdrawing substituents such as CHO, COOR, CN at C-7 tend to shift the equilibrium to the norcaradiene side (Table 1, entry 2), while the equilibrium is shifted to the cycloheptatriene side by the presence of electron donating substituents, such as OR, NR₂ *etc.* (Table 1, entry 3).^{20,21} Ciganek proposed that an increase in the NC–C–CN angle due to the dipole–

Scheme 2 Rhodium(II) catalysed intramolecular Buchner reaction.

dipole repulsion between the two cyano groups leads to the stabilisation of the norcaradiene form (Table 1, entry 2). Replacing one of the cyano groups with a trifluoromethyl group led to a rapidly equilibrating system that was studied by variable temperature NMR (Table 1, entry 5).²² Analogously, two trifluoromethyl groups on the azulene framework, push the equilibrium almost entirely to the cycloheptatriene (Table 1, entry 4). Kohmoto's studies have shown that the stability of norcaradienes is largely controlled by the nature of the substituent at the C-7 position.^{23–25} With a CO₂Me substituent, the norcaradiene structure is destabilised however, and cleavage of C1–C6 bond is induced by valence isomerisation (Table 1, entry 6).²⁶

The intramolecular Buchner reaction involving aromatic addition reactions of aryl α -diazoketones, effected by rhodium(II) catalysis, leads to a tricyclic norcaradiene, which exists in dynamic equilibrium with the more stable bicyclic cycloheptatriene tautomer through an electrocyclic ring-opening/ring-closing process (Scheme 2). This approach has attracted attention as a versatile route to azulene systems, which are a very interesting series of compounds incorporating CHT–NCD valence isomers.^{7,8,27,28} The synthetic utility of the reaction, particularly in the ability to simultaneously generate multiple stereogenic centres, including a challenging bridgehead centre, in a highly stereoselective fashion, has been demonstrated, most notably in the synthesis of various natural products by McKervy^{29,30} and Mander^{31–33} and more recently by Reisman.^{34,35}

Through careful catalyst and substrate selection, high levels of chemoselectivity and regiocontrol can be exercised. Indeed, the enantioselectivity of the intramolecular Buchner reaction of α -diazoketones can even be sensitive to the nature of the counterion present in the catalyst.³⁶

The effect of catalyst and substituent choice on the efficiency, regio- and diastereoselectivity of the reactions of a range of α - and β -substituted α -diazoketones has been recently reported by the Maguire group.⁴² In addition the dynamic behaviour of methoxyl-substituted azulenes has been described.⁴³

Following Hannemann¹⁹ and McKervy's^{7,8} precedent, NMR spectroscopy is a very useful tool for studying the position of the norcaradiene–cycloheptatriene equilibrium in substituted azulene systems. The tautomeric equilibrium in the azulenes is, in general, rapid on a NMR timescale, and hence, time-averaged ¹H and ¹³C NMR signals are observed for the system at room temperature. The position of the tautomeric equilibrium can be readily estimated from the C(8)H

Scheme 3 PTAD trapping of the norcaradiene tautomer.

^1H NMR and C-8 ^{13}C NMR chemical shifts since the C-hybridisation exists between a sp^2 environment in the cycloheptatriene and a sp^3 environment in the norcaradiene.¹⁹

Key work by Saba,⁴⁴ led to the detection of the two tautomeric forms of azulene **4** using low temperature NMR spectroscopy. Time-averaged signals for the rapid dynamic equilibrium of azulene **4** were detected at 25 °C (δ_{H} C(8)H 3.86 ppm, δ_{C} C-8 82.05 ppm) but lowering the temperature to -95 °C led to the observation of two sets of new signals corresponding to the two tautomeric forms of azulene **4** (Scheme 3). Chemical evidence collected by Saba, also substantiated the existence of the equilibrium by trapping the norcaradiene tautomer in a hetero-Diels Alder reaction with 4-phenyl-1,2,4-triazoline-3,5-dione (PTAD) to give the adduct **5** (Scheme 3).⁴⁴

Herein, we discuss the findings of a systematic NMR study on the impact of varying the steric and electronic characteristics of substituents on the position of the norcaradiene–cycloheptatriene equilibrium in a range of azulenes (Scheme 4). These substituents include:

- a hydrogen or a methyl group (R^2) at the bridgehead position
- alkyl groups (R) with varying steric demands at positions C-2 and C-3
- a methoxy substituent (X) on the ring system.

A series of room temperature (rt) and variable temperature (VT) ^1H and ^{13}C NMR spectroscopy experiments was conducted as described below.

Results and discussion

A series of azulenes with varying substituents R , R^2 and X , designed to enable exploration of the influence of substitution on the norcaradiene–cycloheptatriene tautomeric equilibrium, were prepared by efficient rhodium(II) catalysed cyclisation of the precursor α -diazoketones, derived from the appropriate carboxylic acid, following previously reported methodology (Scheme 4).^{42,43,45,46} With substituents (R) in the linker chain of the diazoketones, the resulting azulenes can be formed in two diastereomeric forms. In practice, the major diastereomer of azulenes substituted at C-2 is the *cis*-azulene (C-2 relative to C-8a) while the *trans*-azulene (C-3 relative to C-8a) is the major product of the C-3 substituted azulenes due to a conformational preference in the transition states for the aromatic addition.^{45,47} In many instances, and particularly with sterically demanding groups at position C-3, the azulenes are formed as single diastereomers. The overall diastereoselectivity is sensitive to the nature of the rhodium catalyst.^{36,42,48}

The effect of substitution at the bridgehead position, R^2 (Scheme 4) has been demonstrated in compounds **6–13**. The bridgehead unsubstituted azulenes **6**, **8**, **10** and **12** derived from the corresponding terminal diazoketones are relatively labile compounds and decompose at room temperature within days. Furthermore, they rearrange on exposure to silica gel to conjugated trienone systems (Scheme 5).

Treatment with trimethylamine yields the same result. The rearrangement of the unconjugated azulene on treatment with silica gel, to the more thermodynamically stable isomer, has previously been reported by Scott for the unsubstituted azulene **6**.⁴⁹

In contrast, the presence of a bridgehead methyl group stabilises the azulenes so that they can be purified by chromatography. Furthermore, increasing the steric demand at C-2 and C-3 ($\text{R} = \text{Me}$, Et , $n\text{-Pr}$, $i\text{-Pr}$, $n\text{-Bu}$, $t\text{-Bu}$) results in an increase in stability of the azulenes and indeed the substi-

Scheme 4 Cyclisation of precursor α -diazoketones leads to an equilibrating norcaradiene–cycloheptatriene product; major and minor diastereomers shown in each case.

Scheme 5 Rearrangement of bridgehead-unsubstituted azulenones to a conjugated trienone.

tuted versions are much easier to handle and store than the parent compounds.

Based on Hanneman's analysis, the chemical shift of C(8)H in the cycloheptatriene tautomer is estimated at δ_{H} 5.2–5.3 ppm, while the norcaradiene is estimated at δ_{H} 2.8–3.5 ppm. In all cases, the observed spectroscopic details are time-averaged when recorded at room temperature, and therefore the position of the tautomeric equilibrium is estimated on Hannemann's basis and included in the tables below. *The relative percentages of the cycloheptatriene present are indicative of the trends rather than absolute and should be considered accordingly.*

Bridgehead substitution at C-8a

The parent azulenone **6**, first described by Scott,^{28,49} and McKervery,^{7,8} is a useful starting point in an NMR study of this dynamic equilibrium, existing almost entirely as the cycloheptatriene, with the proton chemical shift of the C(8)H signal occurring at δ_{H} 5.06 ppm. Bridgehead substitution of the proton at C-8a with a methyl group results in a shift towards the norcaradiene structure **7** (Table 2, entry 1), which can be

rationalised by conformational effects – the bridgehead methyl has the effect of bringing the C-3a and C-8 closer together, resulting in a stabilisation of the norcaradiene (Fig. 3).⁵¹ This effect is further demonstrated in the substituted derivatives, particularly the alkyl substituted azulenones (Table 2, entries 2–4).

As illustrated in Table 2, when the bridgehead substituent $\text{R}^2 = \text{H}$, variation of the substituent at C-3 does not have a significant influence on the position of equilibrium. However, this is altered when $\text{R}^2 = \text{Me}$, where C-3 alkyl substitution results in a significant shift towards the norcaradiene. Furthermore, as the steric demand of the C-3 substituent increases, the equilibrium is increasingly shifted towards the norcaradiene form, albeit with modest differences (H to allyl to ethyl). In the case of the *geminal*-dimethyl substituted derivatives **12** & **13** (Table 2, entry 4), a similar effect is evident with a dramatic increase in the norcaradiene tautomer when the bridgehead methyl substituent is introduced.

Alkyl substitution at C-2 and C-3

Key spectroscopic data for C-2 and C-3 substituted azulenones is summarised in Tables 3 and 4 and our discussion will focus initially on the major diastereomers in each instance, *i.e.* *cis*-C-2–C-8a and *trans*-C-3–C-8a. Substitution at C-3 shifts the position of equilibrium towards the norcaradiene relative to the unsubstituted azulenone **7**, as illustrated in Table 3. In contrast, substitution at position C-2 has little impact relative to the unsubstituted analogue and results in a slightly increased preference for the cycloheptatriene structure (compare Tables 3 and 4). Thus, the position of the norcaradiene–cycloheptatriene equilibrium is less sensitive to the substituent in the C-2 substituted azulenones than for the C-3 substituted azulenones (compare Table 3, entries 2–5 with Table 4, entries 2–5). As the C-2 alkyl substituent is more remote from the interconverting norcaradiene–cyclohepta-

triene ring systems than the C-3 alkyl substituent, this observation is readily rationalised on conformational grounds. Interestingly, the magnitude of the coupling constants (J) of the

C(8)H is larger when the signal appears further downfield, consistent with increased sp^2 character at C(8)H in the cycloheptatriene tautomer.

Interestingly, a distinctive steric effect is observed in the C-3 alkyl substituted azulenone series, which is not observed for the corresponding C-2 substituted analogues; as the alkyl substituent increases in size from methyl to ethyl to n -alkyl, a small but detectable shift towards the norcaradiene form is observed, (cf. Fig. 4 and compare Table 3, entries 1–5 with Table 4, entries 1–5). However, with the more sterically demanding t -butyl and geminal-dimethyl groups at position C-3, a conformational change is evident and the position of

While the minor *trans*-diastereomers are seen with the C-2-alkyl azulenones the phenyl and benzyl derivatives 29 and 30 are formed exclusively as the *cis*-diastereomer (entries 6&7). ^b Chemical shifts reported in ppm measured at rt.; coupling constants in Hertz; literature references describing the synthesis and characterisation of each of the azulenones included above. ^c Signal not detected.

Fig. 4 Effect of substitution at C-3 and C-2 on C(8)H ^1H NMR chemical shift relative to the unsubstituted azulene 7.

equilibrium is essentially frozen by the steric demands of the bulky substituents (Table 3, entries 7 & 10). The position of equilibrium for these azulenes is essentially equivalent to that of the unsubstituted azulene 7 (Table 3, entry 1) in that they contain almost equal mixtures of the two tautomers. Intermediate effects are seen with an isopropyl substituent (Table 3, entry 5). Where detected, the ^{13}C NMR chemical shifts of the C-8 carbons mirror the observed trends, showing a distinctive shift due to the changing hybridisation of the carbons involved in the equilibration process.

The stereochemistry at C-2, C-3 and C-8a

As illustrated in Fig. 4, the stereochemistry of the substituents at positions C-2 and C-3 relative to C-8a methyl has a bearing on the position of the norcaradiene–cycloheptatriene equilibrium. In the C-3 substituted azulenes, which are formed predominantly as *trans*-diastereomers, the equilibrium lies towards the norcaradiene relative to the unsubstituted azulene 7; while for the minor *cis*-diastereomers, there is a downfield shift of the C(8)H signal towards the cycloheptatriene. In the C-2 substituted series, for both the *cis*- and *trans*-azulenes, the position of equilibrium lies more towards the cycloheptatriene than in the unsubstituted azulene 7, with the effect being stronger for the minor *trans*-azulenes, 26–30. Furthermore, the coupling constant (J) for the C(8)H signal is a little larger for the *minor* diastereomers reflecting the different conformation of the two diastereomers based on the position of equilibrium.

For each of the minor diastereomers (*cis*-C-3 substituted and *trans*-C-2 substituted), the position of equilibrium is less sensitive to substituent bulk in both cases with little or no shift in equilibrium for C-2 substituted azulenes (Fig. 5) and a small shift towards the cycloheptatriene with increased steric demand at C-3 for the C-3 substituted azulenes (Table 3). Steric strain between the alkyl substituent and the C(4)H in the *cis*-C-3 norcaradiene destabilise this tautomer, while the presence of the alkyl substituent at position C-3 in the major *trans*-C-3 azulenes conformationally favours the norcaradiene tautomer by bringing C-3 and C-8 closer together (Fig. 5).

Fig. 5 Conformational preference for NCD tautomer in C-3 substituted azulenes.

Variable temperature NMR spectroscopy studies

In an attempt to resolve the signals of the equilibrating structures into those of the individual tautomers, a series of variable temperature ^1H and ^{13}C NMR studies were conducted on selected azulene systems (Table 5). All studies were conducted in deuterated dichloromethane and typically the temperature was lowered in steps of 10 K from 300 K down to as low as 180 K, depending on the specifications of the system used. A reduction in temperature leads to a slowing down of the rate of interchange between the tautomers which is often observed as a broadening of the ^{13}C C-8 [and in some cases the C(8)H] signal. With sufficient cooling, it was anticipated that separate

signals would be observed for the individual tautomers, reflecting the population of the norcaradiene and cycloheptatriene forms at different temperatures.

The C-3 alkyl substituted azulenes **19** (80:20 *trans*:*cis*, also pure *trans*), **20** (*trans*), **21** (*cis* and *trans* analysed individually) and **22** (*trans*), together with the unsubstituted azulene **7** were initially studied, in an attempt to resolve the respective tautomers (Table 5, entries 1 and 5–8 & Fig. 6). Focussing initially on the major *trans* diastereomers of azulenes **19**, **20** and **21**, as illustrated in Fig. 7, upon reduction of the temperature to 193 K, 180 K and 192 K respectively, the key signals of the C(8)H, in each case, broaden as the temperature is reduced, as anticipated. While complete resolution of the individual tautomers was not observed at lowest temperature, since the slow-exchange limit was not reached, the study did nonetheless provide some interesting and unanticipated results, with the spectra of **19**, **20** and **21** showing a significant upfield shift of the C(8)H proton signal at lower temperature, indicating an increase in the norcaradiene tautomer. While alteration of chemical shift with variation of temperature is well known, the extent of the variation in this case is much greater than could be rationalised solely on this basis. This effect was greatest in the analysis of *trans*-**20**, which exists as an almost equimolar mixture of tautomers at room temperature but showed a dramatic upfield shift of the C(8)H signal to δ_{H} 2.70 ppm (est. 0–5% CHT) upon cooling, indicating an increased preference for the norcaradiene tautomer at reduced temperature. Broadening of the C(8)H signal was also observed on cooling until coalescence occurred at 210 K and by 180 K a broad singlet at δ_{H} 2.70 ppm, assigned to the C(8)H signal, had appeared. Further decrease in temperature is likely to reach the slow exchange limit and to thus afford tautomeric resolution as the peaks are broad even at low temperature.

Additional evidence to support the assignment of the norcaradiene tautomer was provided by ^{13}C NMR spectroscopy showing the disappearance of the broad C-8 signal (84 ppm at 300 and 240 K) by 180 K and the detection of four distinct, albeit broadened, alkene signals at 122.7, 124.4, 126.5 and 130.0 ppm.

Interestingly, the signals for the minor *cis*-azulenes **19** and **21** displayed only a minor shift on decreasing the temperature (Table 5, entries 5 and 6); once again resolution of the signals for the interconverting tautomers was not achieved at low temperature. VT-NMR studies on the C-3 *t*-butyl substituted azulene **22**, behaved very differently. In this case only the *trans*-isomer is present as the synthesis is highly stereoselective in the presence of the bulky *t*-butyl substituent. On decreasing the temperature, as illustrated in Fig. 7, the signal for the C(8)H broadened significantly indicating a decreased rate of interconversion, but crucially in this instance there was no detectable shift in the position of equilibrium with temperature, in direct contrast to the outcome with the C-3 *n*-Pr and *n*-Bu substituted analogues. It is clear from a combination of the room temperature and VT-NMR studies that the presence of the sterically demanding *t*-butyl substituent at the C-3 position in **22** has a dominant conformational impact on the structure such that the norcaradiene–cycloheptatriene equilibrium is, in this case, essentially frozen with little sensitivity to temperature or other factors.

Variable temperature studies of the norcaradiene–cycloheptatriene equilibrium usually focus on reaching the slow exchange rate of the interconversion and thus resolving the NMR signals for the two individual tautomers; our observation that the position of equilibrium shifts significantly towards the norcaradiene on lowering the temperature of the azulene solution, for **19**, **20** and **21**, is an unusual outcome (Fig. 6).²⁷

The impact of temperature on the position of equilibrium was smaller in the case of the unsubstituted azulene **7**, which showed a shift towards the norcaradiene tautomer of approx. 10% at 213 K. The C(8)H signal was undetectable below this temperature and complete resolution of the tautomers was not observed in our study.

We subsequently explored the C-2 alkyl substituted azulenes **4**, **28**, **30**, derived from the α -substituted diazoketones (Table 5, entries 2–4 & Fig. 6) and once again resolution of the individual tautomers of the azulenes was not observed, since the slow exchange rate of the interconversion was not reached (Fig. 8). In each case only the *cis*-isomer is present as the synthesis is highly stereoselective (dr >98:2).⁴² The extent of shift of the C(8)H was less than that observed with the C-3 alkyl series, **19**–**22** but significant nonetheless at approx. 15%, 10% & 20% respectively. These shifts are analogous to that encountered for the unsubstituted azulene **7**, and show that the position of equilibrium is somewhat less temperature dependant in the C-2 substituted series. This is consistent with the fact that the C-2 alkyl substituent is more remote than the C-3 alkyl substituent from the dynamic norcaradiene–cycloheptatriene ring system resulting in reduced entropic impact on the position of equilibrium.

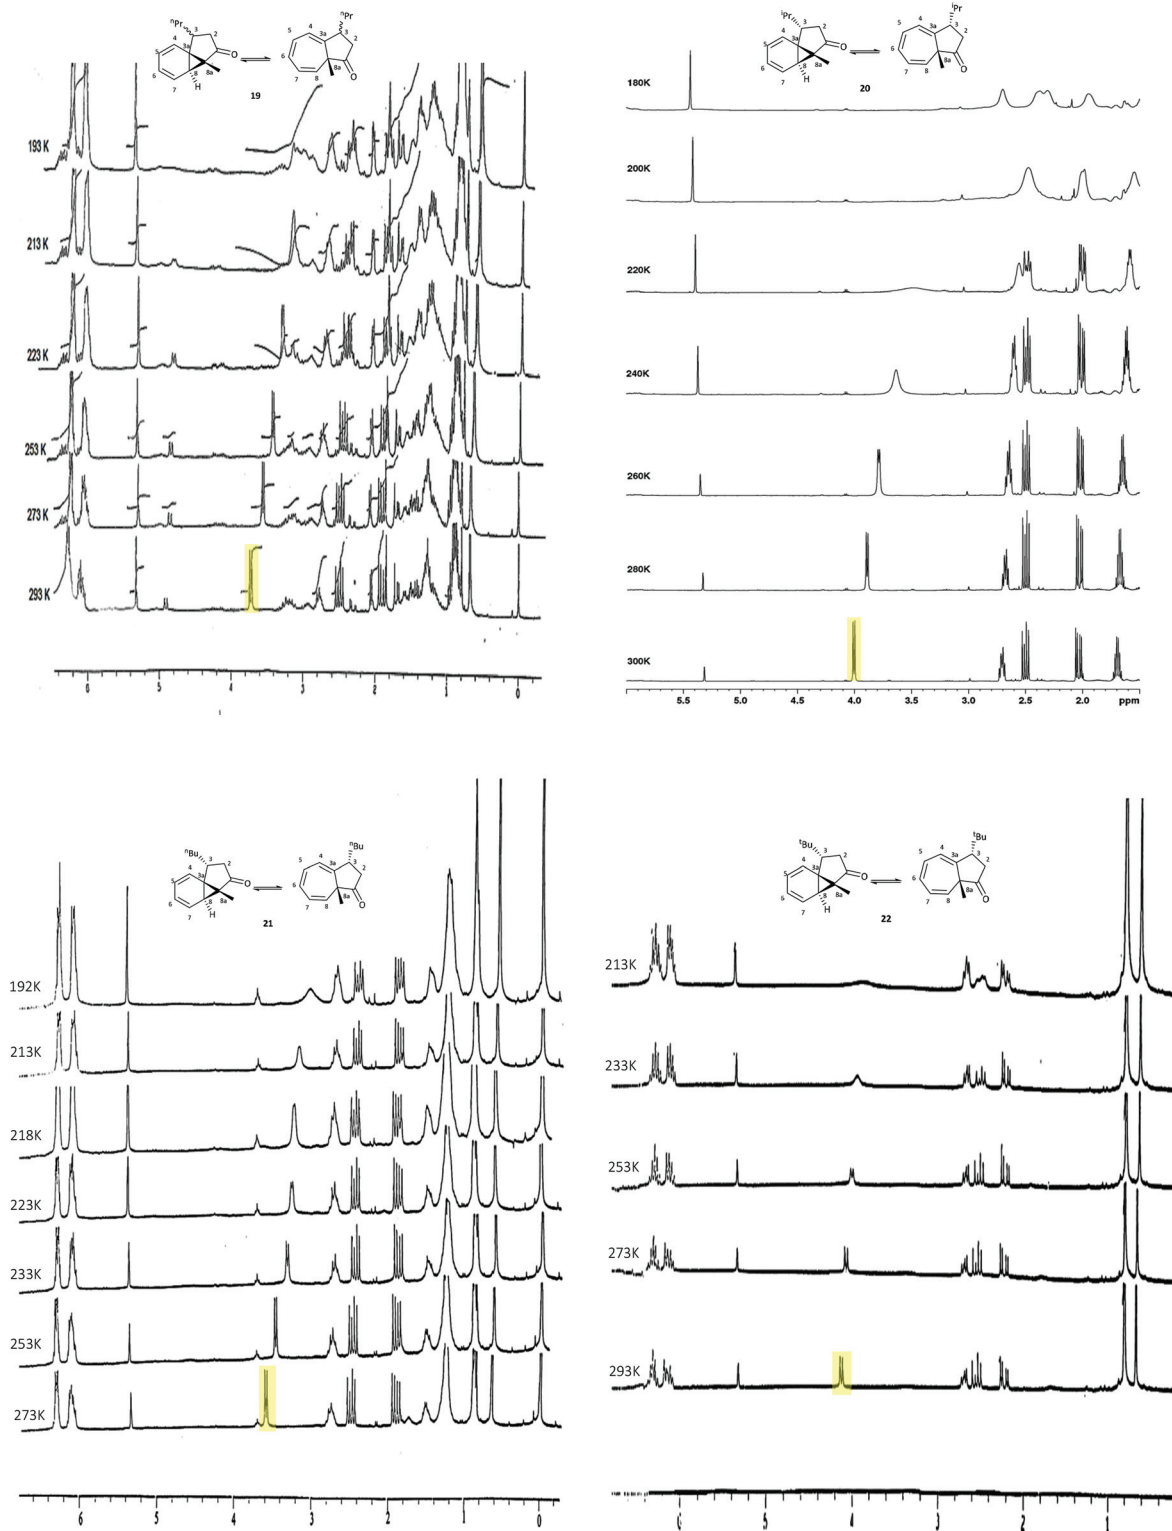

Fig. 7 Variable temperature ^1H NMR spectra of the azulenes **19** (*trans* : *cis* 80 : 20) (270 MHz), *trans*-**20** (500 MHz), *trans*-**21** (270 MHz), *trans*-**22** (270 MHz) recorded in CD_2Cl_2 ; C(8)H highlighted.

Previous work within our group observed the dynamic equilibria of the C-6 methoxy azulenes *cis*-**31** and *cis*-**32**, by variable temperature NMR (Table 6).⁴³ These azulene systems

are complex: in parallel with the equilibrium between the norcaradiene and cycloheptatriene tautomers, interconversion of the *trans*- and *cis*-diastereomers occurs simultaneously. Similar

^a Observation of the resolution of the individual NCD/CHT signals if slow exchange limit was reached. ^b Position of equilibrium influenced by temperature. Estimation based upon Hannemann's principle;¹⁹ values estimate change in position of equilibrium using δ_{H} C(8)H at rt and at low T (180–218 K depending upon spectrometer). Signals for the *cis*-isomers were undetectable below 273 K. ^c Diastereomeric ratio (*trans* : *cis*) influenced by temperature. ^d Analysed as a mixture (80% *trans*-31, 80% *trans*-32, 94% *trans*-33).

to the C-3 substituted systems, resolution of the signals due to the tautomers of each azulenone was not observed since the slow exchange rate of interconversion was not reached, but again some interesting trends were recorded. Decreasing the temperature resulted in an upfield shift in the position of the C(8)H signal of the *trans* diastereomer, indicating an increased preference for the norcaradiene tautomer at reduced temperatures, in line with the observations noted earlier for azulenones 19 and 21 (Table 5). More significantly, an increase in the ratio of *trans* : *cis* azulenone was observed.

Azulenone 33⁴³ was analysed as a mixture of diastereomers (*trans* : *cis*, 94 : 6) (Table 6, entry 3). At 300 K, the major *trans*-azulenone C(8)H signal is observed at 3.90 ppm, indicating that the equilibrium contains ~45% of the cycloheptatriene tautomer. Coalescence is observed for *trans*-33 at 260 K and resolution of the signals corresponding to both tautomers is achieved by 183 K as the slow exchange limit of the system is reached, where separate doublets are observed at 2.85 ppm and 5.62 ppm for the norcaradiene and cycloheptatriene (Fig. 9). Thus, for the first time in this series, signals for the two interconverting tautomers were successfully resolved by ^1H NMR spectroscopy, analogous to Saba's report.⁴⁴ A more complete analysis of the position of the signals attributed to each component is given in Table 7.

The ability to observe the signals of the two individual tautomers of *trans*-33, while the slow exchange limit was not reached for the azulenones 4, 20, 28 and 30 by 180 K warrants consideration. This is most likely due to the presence of

Fig. 9 Variable Temperature ^1H NMR stacked plot of azulene **33** (CD_2Cl_2 ; 500 MHz); *trans*-NCD **33** (blue), *trans*-CHT **33** (red), *cis*-NCD **33** (green).

the sterically demanding *t*-butyl group, which inhibits the rate of interconversion sufficiently such that at 183 K the slow exchange limit is achieved. As further evidence, in working

with the azulene **33** there was a very significant difference in the rate at which equilibration of the *cis* and *trans* isomers took place at room temperature. It took typically 6

^a Spectra recorded in CD_2Cl_2 at 500 MHz.

days for the mixture to reach 96:4 which appears to be the thermodynamic equilibrium for this compound at room temperature. In contrast the *cis*–*trans* interconversion of the methyl substituted derivative **31**, is so fast that we have never observed mixtures at anything other than the thermodynamic ratio 80:20. However, with the isopropyl derivative **32** we have managed to capture NMR spectra with *cis*–*trans* ratios other than the equilibrium 80:20, which is achieved within 21 h (room temperature, CDCl_3) for this compound.⁴³ Accordingly, below room temperature, the rate of *cis*–*trans* interconversion of **33** would be slower, such that an alteration in the *cis*–*trans* ratio would not be observed in the low temperature NMR studies.

The chemical shift of signals due to C(8)H of the minor *cis*-azulenone **33** were barely affected on reduction of the temperature, with no broadening observed. This is rationalised on the basis that *cis*-**33** exists almost entirely as its cycloheptatriene tautomer (C(8)H signal observed at 5.38 ppm, estimated 95–100% CHT) and thus there is no apparent interconversion to slow down.

A ^{13}C NMR spectrum of **33** was also recorded at 183 K, along with COSY and C–H correlation experiments, to allow the complete assignment of the ^{13}C NMR spectrum (Fig. 10).

Fig. 10 ^{13}C NMR spectrum of azulene **33** at 183 K (CD_2Cl_2 ; 500 MHz).

This provides further evidence of the presence of the three components in the NMR mixture at 183 K. Three carbonyl resonances are clearly visible at 218.1, 221.4 and 222.9 ppm corresponding to the norcaradiene tautomer of *trans*-**33**, the cycloheptatriene tautomer of *trans*-**33** and the cycloheptatriene tautomer of *cis*-**33**, respectively. Other significant resonances are the C-8 signals of the norcaradiene tautomer of *trans*-**33** at 36.77 ppm, with the C-8 resonances for the cycloheptatriene tautomer of *trans*-**33** and *cis*-**33** observed at 126.7, which compare well with those reported by Saba.⁴⁴ Interestingly, the resonances for C-4, C-5 and C-7 of *trans*-**33** in the ^{13}C NMR spectrum of **33** at 300 K are significantly broadened, and no signal due to C-8 of *trans*-**33** is observed, which suggests that at this temperature the rate of norcaradiene to cycloheptatriene interconversion of *trans*-**33** is slow on the ^{13}C -NMR time-scale. In contrast, the signals that can be attributed to *cis*-**33** are sharp at this temperature.

Conclusions

In summary, the norcaradiene–cycloheptatriene tautomeric equilibrium in the series of azulenones studied is influenced by both the position and the steric demands of alkyl substituents on the core molecular framework. NMR spectroscopy has enabled rationalisation of the observed trends on the basis of the position and nature of the substituents. In general substituents at C-3 have a stronger impact on the norcaradiene–cycloheptatriene equilibrium than those at C-2, and, furthermore, when the C-3 substituent is *trans*- to the bridgehead methyl group the effect is substantially more evident than for the *cis*-analogues. With the parent unsubstituted azulene **6**, the equilibrium lies very much towards the cycloheptatriene form; introduction of substituents at C(8a) and C-3 (*trans*) result in a substantial shift towards the norcaradiene tautomer. The minor diastereomers of the azulenones, either *cis*- or

trans-structures depending on whether C-3 or C-2 substituted, lie almost entirely on the side of the cycloheptatriene with little sensitivity to substituent size.

Variable temperature NMR studies have shown that the norcaradiene–cycloheptatriene equilibrium in the *trans* C-3 alkyl substituted azulenes, and to a lesser extent the *cis* C-2 substituted derivatives, is sensitive to temperature, showing a shift towards the norcaradiene tautomer at lower temperatures. In contrast, with the *t*-butyl substituent, the equilibrium is unaffected by temperature highlighting the conformational impact of the sterically demanding substituent. Signals for the tautomers of the azulene **33** were successfully resolved at 183 K allowing full characterisation of each structure by ^1H and ^{13}C NMR analysis.

Experimental

^1H and ^{13}C NMR spectra were recorded on a Jeol GSX 270 MHz (^{13}C , 67.8 MHz), Bruker AVANCE 300 MHz (^{13}C , 75.5 MHz), Bruker AVANCE 400 MHz (^{13}C , 100.6 MHz) or Bruker AVANCE 500 MHz (^{13}C , 125.8 MHz) NMR spectrometers. All spectra recorded at room temperature ($\sim 20^\circ\text{C}$) were in deuterated chloroform (CDCl_3). ^1H and ^{13}C NMR spectra were also recorded in deuterated dichloromethane for VT studies. A minor solvent effect was observed for azulene **33**, $\delta_{\text{H-8}}$ (CDCl_3) 3.81 ppm; $\delta_{\text{H-8}}$ (CD_2Cl_2) 3.90 ppm. Chemical shifts (δ) are quoted in parts per million (ppm) downfield from tetramethylsilane and coupling constants (J) in Hertz (Hz). In some cases, ^{13}C NMR spectra were assigned with the aid of DEPT experiments. Synthesis and characterisation of each of the azulenes have been previously described.^{7,42,43,45,48,50}
