# Photochemical synthesis and characterization of novel samarium oxide nanoparticles: toward a heterogeneous Brønsted acid catalyst†

Gregory K. Hodgson,<sup>a</sup> Stefania Impellizzeri,<sup>a</sup> Geniece L. Hallett-Tapley<sup>ab</sup> and Juan C. Scaiano\*<sup>a</sup>

Samarium oxide nanoparticles ( $Sm_2O_3NP$ ) were prepared photochemically for the first time. Characterization shows spherical, polydisperse  $Sm_2O_3NP$  stabilized by 4-HEBA, a substituted benzoic acid. The  $Sm_2O_3NP$  also possess Brønsted acidity. This new material may prove to be a potent heterogeneous acid catalyst.

In the ongoing pursuit of new and useful catalytic materials, nanochemistry has become a popular strategy for discovery and innovation. Widespread research has led to a library of nanoparticle (NP) synthesis techniques, and cutting-edge photochemical methods have recently provided environmentally benign, cost-effective synthetic routes. 1,2 Many nanomaterials consist of well-characterized components possessing catalytic properties that can only be accessed at the nanoscale. In this context, gold and silver NP and nanoclusters are prime examples.3 Other nanocatalysts are modelled after well-performing bulk metal catalysts in an effort to further increase efficiency.4 The lanthanide series remains relatively unexplored, and represents a potentially untapped resource for the development of new nanostructures with as-yet undocumented catalytic properties. Samarium-based compounds may present such an opportunity. As an element, samarium is actually quite abundant<sup>5</sup> and already has some niche applications (e.g. samariumcobalt magnets).6 Samarium triflate is a potent Lewis acid catalyst,7 and SmI2 has been utilized extensively as a versatile reducing agent for single electron transfer reactions.8 Other samarium-based homogeneous catalysts have been employed in the degradation of polychlorinated biphenyls9 and in the dehydration of alcohols.10 Bulk samarium oxide catalyzes the oxidation of methane, ethane and ethylene.11-13 However, little

Novel Sm<sub>2</sub>O<sub>3</sub>NP were prepared photochemically, by UVA irradiation of the benzoin Irgacure-2959<sup>™</sup> (I-2959) photo-initiator in the presence of samarium nitrate hexahydrate (Scheme 1). Similar mechanisms have been used to describe the photochemical synthesis of a variety of metallic and metal-oxide nanostructures.¹ For example, cobalt oxide NP have been prepared by initial photoreduction of CoCl<sub>2</sub> using Irgacure-907,¹<sup>5</sup> followed by air oxidation of the cobalt nanoparticles. However, samarium oxidizes much more readily than cobalt

Scheme 1 Photochemical preparation of  $Sm_2O_3NP$  in CH<sub>3</sub>CN. The small arrow in eqn (2) denotes the eventual reduction of the intermediate to 4-HEBA. In eqn (3), n equals 1 or 2 but not 3, as metallic samarium has not been observed.

is known about the behaviour of samarium and its oxides (Sm<sub>2</sub>O<sub>3</sub> and SmO) at the nanoscale. Of the few examples of samarium oxide NP synthesis in the literature, <sup>13,14</sup> lengthy procedures, safety concerns and supercritical conditions are obvious disadvantages. Faster, safer, environmentally friendly synthetic strategies are required if the potential to use these and other lanthanide-based materials for catalysis is to be investigated further. Here we report a simple photochemical route to novel samarium oxide nanoparticles (Sm<sub>2</sub>O<sub>3</sub>NP) possessing physicochemical properties that have the potential to make this new nanomaterial a potent heterogeneous Brønsted acid catalyst.

and thus we believe that it is never fully reduced to Sm<sup>0</sup>. Although a millimolar concentration of photoinitiator would result in cessation of ketyl radical generation after only minutes of irradiation, a precipitate did not form until much later, at which point the partially reduced samarium precursor had been oxidized to Sm<sub>2</sub>O<sub>3</sub>NP. Dynamic Light Scattering (DLS) was used to monitor the NP growth over time, and indicated an initial stage of rapid growth followed by slower growth over the course of several hours (Fig. S1, ESI†). This experiment demonstrated that oxygen is required for the reaction, and also that reduction and oxidation occur concurrently during the initial phase of Sm<sub>2</sub>O<sub>3</sub>NP formation.

This procedure yielded a flaky brown-orange solid that rapidly settles out of many common solvents, but that is easily suspended in strong, polar aprotic solvents such as DMF and DMSO. For example, zeta potential measurements gave an average value of +23.1 mV in DMSO, indicating moderate colloidal stability. Energy Dispersive X-ray Spectroscopy (EDS) identified the primary constituents of the material to be samarium and oxygen (Fig. S2, ESI†).

X-ray Photoelectron Spectroscopy (XPS) detected samarium exclusively in the +3 oxidation state, confirming that the material is comprised of Sm<sub>2</sub>O<sub>3</sub>. This was evident from the presence of a doublet that dominated the 1050.0-1150.0 eV region of the XPS survey of the material (Fig. S3, ESI†). Peak splitting is well known to be the result of j-j coupling, which in this case gave rise to two intense peaks centred at 1084.0 and 1110.3 eV. These binding energies (BE) correspond to the  $3d_{5/2}$  and  $3d_{3/2}$  states of Sm<sup>3+</sup> present in Sm<sub>2</sub>O<sub>3</sub>, respectively, <sup>13,16-20</sup> consistent with the facile oxidation of samarium to Sm<sub>2</sub>O<sub>3</sub> - the more stable of the two oxides. 18-20 Further, no direct evidence of Sm2+ was obtained (a detailed interpretation of all XPS results is given in the ESI†). Traces of SmO could nonetheless be present, but it would exist as a transient surface species and represent only a minute fraction of the material's composition at any given time. 11,13,17,21 Samarium is redox active, so it is possible that the material may respond to its chemical environment by alternating between Sm<sub>2</sub>O<sub>3</sub> and SmO to some extent. In any event, quantification of the core level Sm 3d peak data revealed that the material contains roughly 40% samarium by mass.

X-ray diffraction (XRD) showed broad peaks roughly consistent with bulk phase Sm<sub>2</sub>O<sub>3</sub> (Fig. S4, ESI†). 10,13,22 Peak broadening is a direct result of NP formation and is commonly associated with amorphous solids. 13,17,22,23 SEM revealed remarkably spherical, polydisperse particles with a mean diameter of 417  $\pm$  114 nm (Fig. 1). This value was obtained by manually sizing 450 individual NP from a single SEM image using ImageJ software (Fig. S5 ESI†). Dynamic Light Scattering (DLS) performed on the same batch of Sm<sub>2</sub>O<sub>3</sub>NP (in DMSO) gave a larger mean diameter of 510  $\pm$  122 nm (Table S1, ESI†). Although the magnitudes of the standard deviation in the SEM and DLS results put the two values within range of one another, the mean hydrodynamic diameter being greater than the mean diameter obtained by SEM analysis allows for the possibility that ligands may be coordinated to the NP surface. The most likely candidate for such a stabilizer is 4-(2-hydroxyethoxy)benzoic acid (4-HEBA) formed during Sm<sub>2</sub>O<sub>3</sub>NP synthesis

Fig. 1 Upper panel: SEM image of Sm<sub>2</sub>O<sub>3</sub>NP. Lower panel: histogram showing the size distribution of Sm<sub>2</sub>O<sub>3</sub>NP based on manual analysis of SEM results

(Scheme 1). This compound has previously been identified as a photoproduct of I-2959 and is known to contribute to NP stability. The formation of 4-HEBA under ambient conditions is generally considered to involve trapping of the acyl radical by oxygen, formation of an intermediate peracid, and eventual reduction to 4-HEBA.1 1H NMR spectroscopy performed on Sm<sub>2</sub>O<sub>3</sub> dissolved in DMSO-d<sub>6</sub> detected 4-HEBA even after extensive washing (Fig. S6 and S7 ESI†). No other organic species were detected in the <sup>1</sup>H NMR spectrum but elemental analysis concluded that the material is comprised of 38% carbon and 4.5% hydrogen (Table S2, ESI†). The presence of 4-HEBA accounts for the 38% carbon, which was also qualitatively detected by XPS. However, the molar quantity of 4-HEBA could not be reliably determined from core level C 1s XPS data due to probable sample contamination from adsorbed atmospheric carbon that could enhance the measured intensity of the C 1s peak.

In order to ensure that the individual Sm<sub>2</sub>O<sub>3</sub>NP shown in Fig. 1 are not comprised of smaller NP subunits, TEM imaging was performed and showed no evidence of any internal structure or defects in the NP surface (Fig. S8, ESI†). Efforts to decrease the average size and polydispersity of the Sm<sub>2</sub>O<sub>3</sub>NP by altering the synthetic conditions were unsuccessful. Similarly, any NP too small to be obtained via centrifugation of the post**RSC Advances** 

irradiation solution could not be harvested using a non-solvent approach; adding an excess of toluene to a concentrated volume of supernatant after centrifuging out the larger Sm<sub>2</sub>O<sub>3</sub>NP did not result in precipitation, even after several days at 4 °C. Laser drop ablation of a suspension of Sm<sub>2</sub>O<sub>3</sub>NP in MilliQ H<sub>2</sub>O did produce a small number of NP of diameter less than 50 nm but did not reduce the level of polydispersity (Fig. S9, ESI†). The optimal conditions for laser drop ablation, subsequent washing of the sample and the overall efficiency of the process require further investigation, and will be reported along with any observed effects of size and polydispersity upon the catalytic activity of Sm<sub>2</sub>O<sub>3</sub>NP.

Since 4-HEBA is only mildly acidic (p $K_a \approx 4$ ), its presence alone does not explain the level of acidity possessed by Sm<sub>2</sub>O<sub>3</sub>NP. Hammett indicator studies conducted using a 0.1% w/v solution of dicinnamalacetone (DCA) in toluene suggested that the  $Sm_2O_3NP$  have a  $pK_a \le -3$ . Unfortunately, other common indicators with  $pK_a$  values less than -3, such as benzalacetophenone (p $K_a$  -5.6) and anthraquinone (p $K_a$  -8.2), are colourless in the base form and yellow in the acid form.25 The colour change is undetectable when these indicators are exposed to the brown-orange Sm<sub>2</sub>O<sub>3</sub>NP. Therefore, the amount by which the p $K_a$  of Sm<sub>2</sub>O<sub>3</sub>NP falls below -3 cannot be experimentally determined using the Hammett indicator method. However, since DCA changes from yellow to red upon exposure to an acid, the total number of acid sites per gram of material can be estimated by titration of the solid acid with *n*-butylamine following exposure to the indicator. This experiment required 40 μL 0.1 M n-butylamine (in toluene) to titrate 5 mg of Sm<sub>2</sub>O<sub>3</sub>NP previously exposed to 1 mL 0.1% w/v DCA in toluene, corresponding to a total acid strength of 0.8 mmol g<sup>-1</sup>.

Since the titration method does not differentiate between Brønsted and Lewis acid sites, the acidity of the Sm<sub>2</sub>O<sub>3</sub>NP was also investigated using Fourier transform infrared (FTIR) spectroscopy. By comparing the FTIR spectrum of a solid acid before and after the adsorption of pyridine, the presence of Brønsted acid sites can be detected. With the correct experimental setup, the number of acid sites of each type can also be quantified by this method. Peaks in the FTIR spectrum in close proximity to 1540 cm<sup>-1</sup> and 1440 cm<sup>-1</sup> can often be attributed to the pyridinium ion formed upon adsorption of pyridine to Brønsted and Lewis acid sites, respectively.25 As shown in Fig. 2, saturation of Sm2O3NP with pyridine vapours resulted in the appearance of a band at 1540 cm<sup>-1</sup>, indicating the presence of Brønsted sites strong enough to interact with pyridine. The fullscale FTIR spectra of Sm<sub>2</sub>O<sub>3</sub>NP before and after exposure to pyridine are available in the ESI (Fig. S10 and S11†).

In this case the small signal at 1440 cm<sup>-1</sup> is not evidence of Lewis acid sites; the FTIR spectrum of pyridine showed a strong signal in that same position (Fig. S12, ESI†). However, the latter does not contain any signal in 1490-1570 cm<sup>-1</sup> region, supporting evidence for the presence of Brønsted acid sites on the surfaces of Sm<sub>2</sub>O<sub>3</sub>NP. Overall, the Hammett acid indicator test, n-butylamine titration and pyridine adsorption experiments collectively demonstrated that the Sm<sub>2</sub>O<sub>3</sub>NP have a p $K_a \le -3$ , a total acid strength in the vicinity of 0.8 mmol g<sup>-1</sup> and possess some degree of Brønsted acidity.

Fig. 2 FTIR spectrum of Sm<sub>2</sub>O<sub>3</sub>NP before (a) and after (b) saturation with pyridine vapours. The vertical dashed line at 1540 cm<sup>-1</sup> denotes the position of the characteristic pyridinium ion peak attributable to pyridine adsorbed onto Brønsted acid sites.

As a proof-of-concept, we show that Sm<sub>2</sub>O<sub>3</sub>NP can efficiently protonate the halochromic coumarin-oxazine molecular assembly 1. The absorption spectrum of 1 in CH<sub>3</sub>CN shows a band centred at 410 nm. The addition of an acid opens the oxazine ring and generates the stable fluorescent compound 2 (Fig. S13, ESI†). Within this transformation, the coumarin functionality is brought into conjugation with the cationic unit, bathochromically shifting the absorption band of the generated species by 180 nm.23,24 A fluorescence band centred at 645 nm

Fig. 3 Upper panel: ring-opening of the halochromic switch. Lower panel: absorption spectra of 1 (10 μM, CH<sub>3</sub>CN, 25 °C) before (a) and after (b) 30 min exposure to  $Sm_2O_3$  NP and subsequent centrifugation. Emission spectrum ((c)  $\lambda_{Ex} = 570$  nm, CH<sub>3</sub>CN, 25 °C) of **1** after 30 min exposure to Sm<sub>2</sub>O<sub>3</sub> NP and subsequent centrifugation.

500 nm

Fig. 4 SEM image of  $Sm_2O_3NP$  after repeated exposure to 2 mM NaOH and subsequent washing with  $CH_3CN$ .

can then be observed by selectively exciting 2 at  $\lambda_{\rm Ex}$  570 nm. Therefore, the transformation of 1 into 2, promoted by the addition of a Brønsted acid, can be exploited in order to activate fluorescence and thus permits the investigation of materials with distinctive acidic properties using a simple experimental setup. In this case catalytic conversion to the ring-open form 2 began shortly after exposure to Sm<sub>2</sub>O<sub>3</sub>NP and was complete within 30 min (Fig. 3 and S14, ESI†). This confirmed that Sm<sub>2</sub>O<sub>3</sub>NP possess Brønsted acidity, a property that could make Sm<sub>2</sub>O<sub>3</sub>NP a useful heterogeneous acid catalyst.

In order to confirm that the observed Brønsted acidity of the  $\rm Sm_2O_3NP$  is a surface effect, the impact of exposing  $\rm Sm_2O_3NP$  to a strong base was evaluated.  $\rm Sm_2O_3NP$  previously used to convert 1 to 2 were washed with  $\rm CH_3CN$ , treated with 2 mM NaOH three times, washed again with  $\rm CH_3CN$  and finally exposed to a new 10  $\mu M$  solution of the closed-ring species 1. No conversion from 1 to 2 was observed, even after 24 h (Fig. S15, ESI†). However, the structural integrity of the  $\rm Sm_2O_3NP$  was retained (Fig. 4). This would not be anticipated if protons were being leached from within the NP interior. Interestingly though, the surfaces of base-treated  $\rm Sm_2O_3NP$  shown in Fig. 4 appear roughened or non-uniformly pitted. This may indicate the disruption of several surface oxide layers in close proximity to heterogeneously distributed Brønsted acid sites. In any case, these results confirm the surface acidity of the  $\rm Sm_2O_3NP$ .

#### Conclusions

We describe a photochemical approach to the synthesis of a novel lanthanide-based nanomaterial – Sm<sub>2</sub>O<sub>3</sub>NP – under very mild conditions. To the best of our knowledge, this is the first report of photochemically prepared Sm<sub>2</sub>O<sub>3</sub>NP in the literature. Not only are such methods beneficial from an environmental standpoint, improvements upon traditional synthetic strategies provided by photochemical techniques are necessary to achieve time- and cost-effectiveness that facilitates streamlined production of prototype materials. This in turn permits economic exploration of less than well-travelled regions in terms of the iterative design of new catalytic materials. A

thorough characterization of the physicochemical properties of the  $\rm Sm_2O_3NP$  reported here revealed spherical particles with a 4-HEBA ligand. More importantly, the  $\rm Sm_2O_3NP$  possess surface Brønsted acidity, with a total acid strength of approximately 0.8 mmol  $\rm g^{-1}$ . This property endows the new material with potential as a Brønsted acid catalyst, as illustrated by the  $\rm 1 \rightarrow 2$  conversion. We envision the eventual replacement of harsh homogeneous acid catalysts with  $\rm Sm_2O_3NP$  and similarly designed heterogeneous nanocatalysts offering ease of separation and/or recyclability while maintaining high catalytic efficiency.
