The sol–gel technique followed by conventional (TiO$_2$-1) and hydrothermal (TiO$_2$-2) thermal treatment was employed to prepare TiO$_2$-based photocatalysts with distinct particle sizes and crystalline structures. The as prepared metal oxides were evaluated as photocatalysts for gaseous HCHO degradation, methanol, and dye oxidation reactions. Additionally, metallic platinum was deposited on the TiO$_2$ surfaces and H$_2$ evolution measurements were performed. The photocatalytic activities were rationalized in terms of morphologic parameters along with the electron/hole dynamics obtained from transient absorption spectroscopy (TAS). TiO$_2$-2 exhibits smaller particle size, poorer crystallinity, and higher surface area than TiO$_2$-1. Moreover the hydrothermal treatment leads to formation of the metastable brookite phase, while TiO$_2$-1 exhibits only the anatase phase. TAS measurements show that the electron/hole recombination of TiO$_2$-2 is faster than that of the latter. Despite that, TiO$_2$-2 exhibits higher photonic efficiencies for photocatalytic oxidation reactions, which is attributed to its larger surface area that compensates for the decrease of the surface charge carrier concentration. For H$_2$ evolution, it was found that the surface area has only a minor effect and the photocatalyst performance is controlled by the efficiency of the electron transfer to the platinum islands. This process is facilitated by the higher crystallinity of TiO$_2$-1, which exhibits higher photonic efficiency for H$_2$ evolution than that observed for TiO$_2$-2. The results found here provide new insights into the correlations between thermal treatment conditions and photocatalytic activity and will be useful for the design of high performance photocatalysts.

Introduction

The research in renewable energy sources is intense due to concerns about global warming and other environmental issues related to the huge dependence of the global energy matrix on fossil fuels.$^{1–3}$ Photocatalysis receives particular attention, due to the possibility of harvesting the abundant solar energy and converting it into fuels, such as hydrogen.$^{4–6}$

TiO$_2$-based materials are the most intensely investigated photocatalytic systems following the breakthrough by Fujishima and Honda.$^7$ They exhibit chemical stability, non-toxicity, high reactivity, and can be prepared in different forms and sizes with highly ordered porosity and crystallinity.$^{8–10}$ Typically, the oxide is prepared from a molecular precursor, followed by a thermal treatment to ensure crystallinity. Conventional heating at atmospheric pressure as well as the use of pressurized hydrothermal reactors are the most popular thermal treatments employed.$^{11–15}$

Through the use of molecular engineering, the main limitations of TiO$_2$ have been superposed. For example, visible light activity has been obtained by the introduction of dopants$^{16–20}$ or by the formation of nanocomposites.$^{21–24}$ Moreover, H$_2$ evolution without the necessity of an external bias has been observed in the presence of co-catalysts on the oxide surface.$^{25–28}$

In parallel to the advances of material preparation, large research efforts have been devoted to investigations of well-defined photocatalytic reaction systems and their detailed reaction mechanisms and kinetics using a variety of spectroscopic techniques.$^{29–37}$ Particularly, the use of time-resolved methods, such as transient absorption spectroscopy (TAS)$^{38–41}$ and microwave conductivity measurements (TRMC)$^{42,43}$ has allowed to enhance the fundamental understanding of electron/
hole trapping and recombination, with the latter being recognized as the limiting step of the photocatalytic process.\textsuperscript{44}

Despite the remarkable progress, it is not an easy task to establish clear relationships between the photocatalytic properties and the metal oxide’s morphological and electronic properties. Serpone\textsuperscript{45} and Zhang,\textsuperscript{46} among others\textsuperscript{47,48} have investigated the role of particle size on charge carrier dynamics and photocatalytic activity with the results of these studies being not always similar. More recently, Carneiro and co-workers described the dependence of the methylene blue degradation rate on the concentration of hydroxyl groups and holes at the TiO\textsubscript{2} surface along with their correlations with the particle size.\textsuperscript{49}

In this work, two different TiO\textsubscript{2}-based photocatalysts were prepared by the sol–gel technique, which allows an easy control of the particle size. The as prepared TiO\textsubscript{2} particles were submitted to a conventional thermal treatment at 400 °C in an oven and also to a hydrothermal reactor (200 °C, 12.4 bar), yielding different crystalline phases, surface defects, \textit{etc}. The samples were fully characterized and evaluated by several photocatalytic oxidation tests and also for H\textsubscript{2} evolution, with the aim to provide new insights into the underlying structure–reactivity relationship. The observed photonic efficiencies were rationalized in terms of the morphological properties of TiO\textsubscript{2}-based photocatalysts and the photogenerated charge carrier dynamics studied by nanosecond transient absorption spectroscopy.

**Experimental**

**Materials**

All chemicals were of analytical or HPLC grade and were used as received. TiO\textsubscript{2} photocatalysts were prepared through the hydrolysis of Ti(IV) isopropoxide (Aldrich, 97%). 5 cm\textsuperscript{3} of the alkoxide were dissolved in 30 mL of isopropanol under argon atmosphere. The precursor solution was cooled in an ice bath and, under vigorous stirring, 50 cm\textsuperscript{3} of deionized water were added and the system was exposed to UV-A light (Philips 90 W Hg lamps, 1 mW cm\textsuperscript{-2}) for 8 hours. The resulting pale gray powders were separated by centrifugation and dried at 70 °C under reduced pressure.

**Characterization**

The powders were characterized by X-ray diffraction analysis (XRD) using an XRD6000 powder diffractometer (Shimadzu) operating at 40 kV and 30 mA employing Cu K\textsubscript{a} radiation. The diffractograms were collected between 20 to 90° at 0.5° min\textsuperscript{-1}. Scanning transmission electron microscopy (STEM) images were obtained in an FEI Inspect F50 located at the Brazilian Nanotechnology National Laboratory (LNInano) and operated at 30 kV. N\textsubscript{2} adsorption–desorption isotherms were obtained in an ASAP 2020 analyzer (Micrometrics). The sorption data were analyzed using the Barrett–Joyner–Halenda (BJH) model. Diffuse reflectance measurements were carried out in an UV-1650PC spectrometer (Shimadzu) with the band gap energy being estimated by the Tauc method.\textsuperscript{51}

Transient absorption spectroscopy (TAS) was carried out employing a LKS80 nanosecond laser flash photolyticspectrometer (Applied Photophysics) equipped with the proper diffuse reflectance accessory. The samples were excited in a quartz cuvette by a LPX 200 excimer laser (XeF; \(\lambda_{\text{exc}} = 351 \text{ nm} \)); 14 mJ per pulse) from Lambda Physics. The transient signals were collected by a PMT connected to a computer interfaced to a DSO9064A oscilloscope (Agilent). The data points were converted to absorbance values according to eqn (1), where \(A\) = absorbance; \(I_0\) = analyzing light level; \(I_l\) = light reflected by the absorbing sample; \(I_a\) = light absorbed by the absorbing sample. In these experiments, the samples were employed as dry powders.

\[
\Delta A = \log \left( \frac{I_0}{I_r} \right) = \log \left( \frac{I_0}{I_0 - I_a} \right) \tag{1}
\]

**Photocatalytic studies**

The photocatalytic activity of the as prepared TiO\textsubscript{2} powders was evaluated by different methods and compared to the activity of the well-known photocatalyst Evonik Degussa Aerioxide TiO\textsubscript{2} P25 (TiO\textsubscript{2}–P25). Acetaldehyde photo-oxidation was carried out accordingly to the ISO 22197-2 standard method\textsuperscript{52} in an experimental setup described previously.\textsuperscript{23,53} The active area of the samples was 15 cm\textsuperscript{2}. All samples were cleaned under UV-irradiation (10 W m\textsuperscript{-2}, 365 nm) prior the experiments. The gaseous reaction mixture was prepared by mixing streams of dry air (500 mL min\textsuperscript{-1}), wet air (500 mL min\textsuperscript{-1}, relative humidity of 50%), and 10% of a CH\textsubscript{3}CHO/N\textsubscript{2} mixture (approximately 50 mL min\textsuperscript{-1}) to obtain a final CH\textsubscript{3}CHO concentration of 1 ppm at 297 K. Prior to the photocatalytic tests, the photoreactor was purged with the CH\textsubscript{3}CHO/water vapor/air mixture without illumination until a steady CH\textsubscript{3}CHO concentration was achieved at the reactor outlet. Afterwards, the sample was irradiated for approximately 120 min.

For methanol photo-oxidation, 50 mg of TiO\textsubscript{2} were suspended in 3.0 \(\times\) 10\textsuperscript{-2} mol L\textsuperscript{-1} aqueous methanol solution placed in a round borosilicate reactor. The system was
irradiated using UV-A light \((3.04 \times 10^{-7} \text{ Einstein s}^{-1})\). The amount of formaldehyde produced at different time intervals was determined by the Nash method.\(^{49,54,55}\) The photonic efficiency values \((\xi)\), being defined as the ratio of \(\text{CH}_3\text{CHO} \) degradation or HCHO formation rate and the incident photon flux, were calculated as previously described.\(^{53,56}\)

The activity of the TiO\(_2\) samples was also evaluated through UV-A degradation of the azo-dye Ponceau-4R (P4R) or trisodium (8Z)-7-oxo-8-[(4-sulphonatonaphthalen-1-yl)hydrazinylidene]-naphthalene-1,3-disulphonate. Detailed description of the experimental setup can be found elsewhere.\(^{57}\) The photon flux \((\phi)\) was determined by a radiometric/photometric setup described previously.\(^{58}\)

The degradation rate was evaluated by Total Organic Carbon measurements (TOC) carried out in a Shimadzu TOC-VCPH Analyzer. Control experiments were taken in the absence of any photocatalyst to evidence the role of the TiO\(_2\) on the photochemical reaction. Platinized samples were employed for hydrogen evolution measurements using the experimental setup described previously.\(^{25}\)

Refinement of the XRD data (see Table S1 and Fig. S1–S3 in the ESI\(^{\dagger}\)) reveals that the brookite content is approximately 45\%. The appearance of the brookite phase in the TiO\(_2\) samples prepared by the hydrothermal method agrees with previous studies carried out by Isley and Penn,\(^{59}\) as well as by other authors.\(^{60,61}\) This photocatalyst also exhibits broader diffraction peaks as compared with TiO\(_2\)-1 and the commercial sample (P25), which is in agreement to the smaller particle size observed in the STEM images. Crystallite sizes calculated by the Scherrer equation were 18 nm and 10 nm, respectively, for TiO\(_2\)-1 and TiO\(_2\)-2, similar to the values found by electron microscopy. Moreover, the lattice parameters obtained for TiO\(_2\)-2 (Table S1 \(^{\dagger}\)) indicate a more distorted structure in relation to TiO\(_2\)-1 or TiO\(_2\)-P25, especially in the \(c\) axis.

As expected, both photocatalysts exhibit absorption only in the UV region with an optical bandgap of 3.2 eV, similar to the values reported for TiO\(_2\) anatase.\(^{62}\) Diffuse reflectance spectra of the as prepared powders can be found in the ESI (Fig. S4\(^{\dagger}\)). The samples were also characterized by N\(_2\)-adsorption/desorption isotherms using the B.E.T. method (Fig. S5\(^{\dagger}\)). Type IV sorption curves were observed, according to the IUPAC classification,\(^{63}\) which are characteristic of mesoporous materials. The surface areas calculated for the samples were 66 and

### Results

**Electronic and morphological characterization**

The two TiO\(_2\)-based photocatalysts are constituted of agglomerates of spherical nanoparticles, as visualized in the respective STEM images (Fig. 1). The particle sizes estimated from these images are \((25 \pm 2)\) nm and \((12 \pm 3)\) nm, respectively, for TiO\(_2\)-1 and TiO\(_2\)-2.

XRD analyses of the powders, Fig. 2, show that TiO\(_2\)-1 is constituted only by the anatase polymorph, while TiO\(_2\)-2 exhibits peaks characteristic of anatase and brookite. Rietveld refinement of the XRD data reveals that the brookite content is approximately 45\%. The appearance of the brookite phase in the TiO\(_2\) samples prepared by the hydrothermal method agrees with previous studies carried out by Isley and Penn,\(^{59}\) as well as by other authors.\(^{60,61}\) This photocatalyst also exhibits broader diffraction peaks as compared with TiO\(_2\)-1 and the commercial sample (P25), which is in agreement to the smaller particle size observed in the STEM images. Crystallite sizes calculated by the Scherrer equation were 18 nm and 10 nm, respectively, for TiO\(_2\)-1 and TiO\(_2\)-2, similar to the values found by electron microscopy. Moreover, the lattice parameters obtained for TiO\(_2\)-2 (Table S1 \(^{\dagger}\)) indicate a more distorted structure in relation to TiO\(_2\)-1 or TiO\(_2\)-P25, especially in the \(c\) axis.

As expected, both photocatalysts exhibit absorption only in the UV region with an optical bandgap of 3.2 eV, similar to the values reported for TiO\(_2\) anatase.\(^{62}\) Diffuse reflectance spectra of the as prepared powders can be found in the ESI (Fig. S4\(^{\dagger}\)). The samples were also characterized by N\(_2\)-adsorption/desorption isotherms using the B.E.T. method (Fig. S5\(^{\dagger}\)). Type IV sorption curves were observed, according to the IUPAC classification,\(^{63}\) which are characteristic of mesoporous materials. The surface areas calculated for the samples were 66 and

![Fig. 1](image1.png) **STEM images of TiO\(_2\)-1 (a) and TiO\(_2\)-2 (b) photocatalysts.**
164 m² g⁻¹, respectively, for TiO₂-1 and TiO₂-2. In addition to the higher surface area, the photocatalyst prepared via hydrothermal treatment also exhibits greater porosity, 27%, as compared with 15%, for TiO₂-1.

The morphological characterization of the as synthesized photocatalysts confirmed the expected differences between samples thermally treated in a hydrothermal reactor at relatively low temperature and those treated in a conventional oven. TiO₂-2 exhibits smaller particle size and higher surface area, since it was treated at low temperatures thus avoiding grain boundaries. Another consequence of the hydrothermal treatment at 200 °C is the smaller crystallinity of TiO₂-2 in relation to TiO₂-1, which was sintered at 400 °C and exhibited only anatase XRD patterns, with no signal from the metastable brookite phase.

Photocatalytic activity

The effectiveness of the TiO₂ samples as photocatalysts was evaluated comparing the efficiency of the oxidation of a dye (Ponceau 4R), gaseous acetaldehyde, and methanol, and also the photocatalytic hydrogen evolution through the dehydrogenation of methanol, using platinum as co-catalyst. A summary of the observed rates and the respective photonic efficiencies is presented in Table 1 along with the main morphological data.

In Fig. 3, the time profile of the gaseous CH₃CHO photodegradation is shown using the two photocatalysts prepared here in comparison to the commercial titanium dioxide P25. Apparently, the commercial photocatalyst exhibits a higher efficiency as compared with both samples prepared by the sol-gel method. Among the synthesized powders, TiO₂-2 exhibits the best performance. The same trend is observed for the degradation of the Ponceau 4R dye (time profile TOC curves for the different photocatalysts can be found in the ESI, Fig. S6†).

For the photocatalytic methanol oxidation, the performance of bare TiO₂-2 is higher than that observed for the commercial oxide and approx. 35% better than that observed when using TiO₂-1, Fig. 4. Interestingly, after platinization, the photocatalytic activity of TiO₂-2 decays by 50%, while for TiO₂-1 and P25, the photonic efficiencies increase by 7.5% and 2.4%, respectively.

The time profiles of the photocatalytic hydrogen evolution obtained by mass spectrometry are shown in Fig. 5. For both samples, one can observe a fast increase of the H₂ production rate after the light is turned on. Then, the H₂ evolution rate reaches a plateau and remains almost constant until the irradiation is turned off. The slight decrease on H₂ evolution rate over time is likely related to the decrease of the sacrificial agent concentration. The photocatalytic production of hydrogen follows the same trend as that observed for the methanol oxidation, with TiO₂-1–Pt exhibiting a higher performance than TiO₂-2–Pt. It is worthwhile to note that the efficiency of TiO₂-2 decreases after Pt deposition.

⁴ In μmol s⁻¹. ⁵ In μmol L⁻¹ s⁻¹ g⁻¹.
from trapped electrons and holes, since free charge carriers tend to recombine (or be trapped) at the picosecond time scale.4

Typical transient absorption spectra obtained under N2 atmosphere for the TiO2 photocatalysts prepared here are shown in Fig. 6.

One can observe a peak at 380–500 nm, a broad band between 500 and 700 nm and a further peak at 760–890 nm. For TiO2-1, the high energy absorption maximum exhibits a hypsochromic shift at longer times after the laser excitation, which is not observed for TiO2-2. The introduction of metallic platinum at the photocatalyst surface induces some changes on the transient absorption spectra, as exemplified for TiO2-1 in Fig. 7.

It is well known that metallic platinum acts as electron acceptor on the TiO2 surface, with electrons being transferred within 10 ps.4 Thus, in ns-transient absorption spectra of the TiO2–Pt photocatalysts, the signals from trapped electrons should be greatly reduced in comparison to the bare
photocatalysts. The difference spectrum shown in Fig. 7b thus evidences a strong contribution of the trapped electron absorption between 400 and 650 nm. Below 400 nm and above 700 nm, the transient absorption spectra seem to be dominated by trapped holes. Such interpretations are corroborated by previous studies carried out by Serpone et al.\textsuperscript{45} attributing the transient absorption in the range of 490–650 nm to electrons trapped as Ti\textsuperscript{3+} centers and also in different energy midgap levels. However, absorption features of trapped holes have also been reported in the 400–700 nm region,\textsuperscript{33} overlapping with the contribution of photogenerated electrons and hence making it difficult to identify the individual absorption signatures of the trapped carriers in the investigated spectral range.

Zawadzki\textsuperscript{46} performed calculations based on the Density Functional Theory and assigned the transient hole absorption in the 400–700 nm range to interpolaron transitions from O\textsuperscript{2−} centers located in the bulk to neighboring oxygen lattice sites. This author showed that holes trapped in the bulk are responsible for the lower energy transient absorption signals and that this feature is blue-shifted as the holes migrate to the surface. Hence, these calculations can explain the hypsochromic shift observed for the high energy band in the TiO\textsubscript{2}-1 transient absorption.

The TAS decay traces observed at three selected wavelengths (400, 500, and 780 nm) are presented in Fig. 8 for the bare as well as for the platinized photocatalysts. As shown in Fig. 8c, in the presence of platinum (as electron scavenger), the transient absorption signal at 780 nm does not even decay in the microsecond time-range. This behavior is different to that observed at 400 nm and evidences that the broad band observed in the range between 750 and 890 nm contains a strong contribution of holes located in a different trap state as compared with those responsible for the peak at higher photon energies (Fig. 8a). The lifetime of the photogenerated holes increases considerably once the electrons are transferred to the Pt islands on the oxide surface. This result is qualitatively similar to that reported by Yoshihara et al.\textsuperscript{33} for TiO\textsubscript{2} nanoparticles with diameters of 10–15 nm. These authors observed two transient absorption peaks at 520 nm and 1200 nm, both of which were attributed to trapped holes. The high energy feature was ascribed to holes trapped more deeply than the ones responsible for the transient absorption at 1200 nm. This conclusion is corroborated by the observations made here. The decay at 400 nm is less affected by the presence of metallic platinum than the signal at 780 nm, which is indicative for the assumption that the holes responsible for the lower energy absorption signature are also the main species responsible for the photocatalytic activity.

Other interesting features can be taken from the decay profiles at 400 nm and 500 nm (Fig. 8a and b, respectively). Both decay curves do not exhibit single exponential behavior, with some residual absorption still being observed after 10 \( \mu \)s. Results for the biexponential fits of the transient absorption data are shown in Table 2.

At all investigated wavelengths the decay kinetics of the TiO\textsubscript{2}-2 photocatalyst are approx. 30% faster than those observed for TiO\textsubscript{2}-1. For TiO\textsubscript{2}-2, the decay at 400 nm does not change after platinum deposition, thus the signal can possibly be related to strongly trapped holes that do not contribute to any photocatalytic reaction. For TiO\textsubscript{2}-1, the presence of platinum increases the rate of these decay processes in relation to the bare powder. This can be explained by the migration of holes between different trapping sites, once the electrons have been transferred to the platinum islands.

At 300 nm, where the contribution of trapped electrons is higher, one can observe that the initial decay is faster than that at 400 nm, particularly for the TiO\textsubscript{2}-2 photocatalyst. Such faster decay rate can be clearly seen in the normalized time-resolved absorption spectra (see ESI, Fig. S7 and S8) and can be related to a faster charge carrier recombination rate in this photocatalyst. As can be seen in Fig. 8b and also in the transient spectra (Fig. 6), the relative intensity of the TiO\textsubscript{2}-1 transient absorption between 500 and 600 nm is higher than that in

**Fig. 8** Absorption time profiles of bare and platinized photocatalysts at (a) 400 nm, (b) 500 nm, and (c) 780 nm.
TiO$_2$. Apparently, more electron/hole pairs are recombining in TiO$_2$-2 than in TiO$_2$-1.

The charge carrier dynamics observed for TiO$_2$-2 can be correlated to the hydrothermal treatment applied during its preparation. The low temperature employed (200 °C) should lead to the formation of more defects in the crystalline structure. These defects may act as recombination centers, decreasing the electron/hole lifetime. Another key aspect influencing the efficiency of the charge separation in TiO$_2$ is the particle size. Serpone et al. studied the influence of the particle size on the charge carrier dynamics and found that the fastest recombination rate is observed for the smallest TiO$_2$ nanoparticles. Herein TiO$_2$-2 exhibits the smallest particle size.

**Discussion**

One of the objectives of this work is to establish relationships between the photocatalyst preparation, its morphological and electronic properties, and, finally, its photocatalytic activity. Given the large number of variables and factors that have to be taken into account, such task can be puzzling and it is usually not easy to establish a direct correlation valid for all photocatalysts. However, the data collected herein allow us to determine some interesting features that can be helpful for the development of highly efficient materials for photocatalysis.

The photocatalytic tests performed showed that in comparison to TiO$_2$-1 the TiO$_2$-2 photocatalyst exhibits better efficiencies for dye degradation, gaseous acetaldehyde oxidation, and methanol oxidation. The performance of the photocatalyst prepared via hydrothermal treatment was even better than that observed for the commercial photocatalyst P25 for methanol oxidation. In these experiments, the higher surface area of TiO$_2$-2 seems to play the major role in determining the photocatalytic effectiveness. All these processes involve the transfer of photogenerated holes to adsorbed species or the indirect transfer to an adsorbed water molecule yielding OH radicals at the surface, which will further oxidize the substrate molecules. In both mechanisms, higher surface areas should lead to higher photonic efficiencies and, additionally, faster hole transfer processes should result in increased degradation rates. In the case of the photocatalytic methanol oxidation, the interfacial charge transfer occurs within 300 ps (ref. 4) and partially compensates the faster recombination rate observed for TiO$_2$-2 in relation to TiO$_2$-1.

If we normalize the degradation rates by the surface areas of the respective photocatalysts, the role of the electron/hole dynamics turns more evident. Taking the methanol oxidation, the normalized rates are 12 × 10$^{-2}$, 7 × 10$^{-2}$ and 4 × 10$^{-2}$ μmol L$^{-1}$ s$^{-1}$ m$^{-2}$, respectively for TiO$_2$-P25, TiO$_2$-1, and TiO$_2$-2. These values follow the same trend observed for the electron/hole lifetimes obtained by TAS. Thus, in a given time after excitation, more charge carriers are available on TiO$_2$-1 than on TiO$_2$-2, but as the surface area of the former is lower, fewer molecules are oxidized.

Another interesting relationship that can be established between the TAS data and the photocatalytic activity arises from the comparison of the degradation rates (corrected by the respective surface area) and the relative intensity of the peaks at low and high energy. The ∆A (800 nm)/∆A (400 nm) ratio immediately after the laser pulse is around 0.7 in TiO$_2$-1 and 0.45 in TiO$_2$-2. This decrease is in the same order than that observed for the corrected degradation rates for methanol oxidation and confirms that the holes responsible for the absorption signature at lower energy are the photoactive ones.

The crystal structure as well as the crystallinity also plays an important role for the observed photocatalytic behaviour. Initially, TiO$_2$-2 was expected to exhibit a more efficient charge separation as compared with TiO$_2$-1, as the former contains both, brookite and anatase crystallites in its structure. As reported earlier, the conduction band edge of brookite TiO$_2$ is approx. 0.14 eV more negative than that of anatase, which should impose an energy barrier for the back electron transfer. However, in the case of TiO$_2$-2 the larger amount of defects within its crystalline structure along with its smaller particle size seem to facilitate the charge recombination, reducing the charge carriers available for photocatalytic processes.

Charge carrier recombination can obviously be expected to be dependent on the light intensity employed in the laser experiments and further studies are necessary to understand more deeply the reason of the faster recombination rates observed for TiO$_2$-2. As stated previously, the electron/hole recombination kinetics depend on the number of charge carriers generated per particle, being much faster at very high concentrations of electron/hole pairs in each TiO$_2$ particle. Therefore, it can be expected that light intensity effects will be more evident in TiO$_2$-2 due to its smaller primary particle size. The results found here for the bare photocatalysts are in good agreement with those reported by Carneiro et al. These authors concluded that, for powders consisting of primary particles with 7–15 nm diameter, the surface area and the available adsorption sites play a major role for the photocatalytic performance, while for 15–35 nm particles, the higher hole concentration and the greater crystallinity decreases the dependency on the surface area.

After platinum deposition on the TiO$_2$ surface, the photocatalytic activities for methanol oxidation and H$_2$ evolution increase for TiO$_2$-1 and TiO$_2$-P25, as a result of the improved charge separation efficiency. However, the photonic efficiency of TiO$_2$-2 for methanol oxidation decreases by 50% in relation to the bare photocatalysts with its performance for H$_2$ evolution being the worst among the investigated powders. Metal deposition leads to a decrease of the available adsorption sites on the TiO$_2$ surface, as previously observed for other TiO$_2$-based photocatalysts. In fact, the surface areas of the as synthesized TiO$_2$ powders decrease by ca. 10% after Pt deposition. However as the surface area reduction is observed for all catalysts, the decrease in the TiO$_2$-2 photocatalytic activity should be related to the concentration of charge carriers on each catalyst surface.

For all samples, the presence of platinum leads to a decrease in the charge carrier recombination rates in relation to those of the bare photocatalysts, since the metal islands act as efficient electron acceptors. Therefore, the results indicate that the lower crystallinity and the reduced particle size of TiO$_2$-2 lead to a smaller concentration of electrons effectively transferred to the

2. TiO$_2$. 
3. Discussion. 
4. If we normalize the degradation rates by the surface areas of the respective photocatalysts, the role of the electron/hole dynamics turns more evident. Taking the methanol oxidation, the normalized rates are 12 × 10$^{-2}$, 7 × 10$^{-2}$ and 4 × 10$^{-2}$ μmol L$^{-1}$ s$^{-1}$ m$^{-2}$, respectively for TiO$_2$-P25, TiO$_2$-1, and TiO$_2$-2. These values follow the same trend observed for the electron/hole lifetimes obtained by TAS. Thus, in a given time after excitation, more charge carriers are available on TiO$_2$-1 than on TiO$_2$-2, but as the surface area of the former is lower, fewer molecules are oxidized.

Another interesting relationship that can be established between the TAS data and the photocatalytic activity arises from the comparison of the degradation rates (corrected by the respective surface area) and the relative intensity of the peaks at low and high energy. The ∆A (800 nm)/∆A (400 nm) ratio immediately after the laser pulse is around 0.7 in TiO$_2$-1 and 0.45 in TiO$_2$-2. This decrease is in the same order than that observed for the corrected degradation rates for methanol oxidation and confirms that the holes responsible for the absorption signature at lower energy are the photoactive ones.

The crystal structure as well as the crystallinity also plays an important role for the observed photocatalytic behaviour. Initially, TiO$_2$-2 was expected to exhibit a more efficient charge separation as compared with TiO$_2$-1, as the former contains both, brookite and anatase crystallites in its structure. As reported earlier, the conduction band edge of brookite TiO$_2$ is approx. 0.14 eV more negative than that of anatase, which should impose an energy barrier for the back electron transfer. However, in the case of TiO$_2$-2 the larger amount of defects within its crystalline structure along with its smaller particle size seem to facilitate the charge recombination, reducing the charge carriers available for photocatalytic processes.

Charge carrier recombination can obviously be expected to be dependent on the light intensity employed in the laser experiments and further studies are necessary to understand more deeply the reason of the faster recombination rates observed for TiO$_2$-2. As stated previously, the electron/hole recombination kinetics depend on the number of charge carriers generated per particle, being much faster at very high concentrations of electron/hole pairs in each TiO$_2$ particle. Therefore, it can be expected that light intensity effects will be more evident in TiO$_2$-2 due to its smaller primary particle size. The results found here for the bare photocatalysts are in good agreement with those reported by Carneiro et al. These authors concluded that, for powders consisting of primary particles with 7–15 nm diameter, the surface area and the available adsorption sites play a major role for the photocatalytic performance, while for 15–35 nm particles, the higher hole concentration and the greater crystallinity decreases the dependency on the surface area.

After platinum deposition on the TiO$_2$ surface, the photocatalytic activities for methanol oxidation and H$_2$ evolution increase for TiO$_2$-1 and TiO$_2$-P25, as a result of the improved charge separation efficiency. However, the photonic efficiency of TiO$_2$-2 for methanol oxidation decreases by 50% in relation to the bare photocatalysts with its performance for H$_2$ evolution being the worst among the investigated powders. Metal deposition leads to a decrease of the available adsorption sites on the TiO$_2$ surface, as previously observed for other TiO$_2$-based photocatalysts. In fact, the surface areas of the as synthesized TiO$_2$ powders decrease by ca. 10% after Pt deposition. However as the surface area reduction is observed for all catalysts, the decrease in the TiO$_2$-2 photocatalytic activity should be related to the concentration of charge carriers on each catalyst surface.

For all samples, the presence of platinum leads to a decrease in the charge carrier recombination rates in relation to those of the bare photocatalysts, since the metal islands act as efficient electron acceptors. Therefore, the results indicate that the lower crystallinity and the reduced particle size of TiO$_2$-2 lead to a smaller concentration of electrons effectively transferred to the
Pt islands. It has previously been shown that the so-called antenna mechanism provides an important pathway for H₂ evolution on Pt-TiO₂ photocatalysts. This mechanism is based on the interparticle charge carrier transport within TiO₂ agglomerates until the electrons reach the Pt islands (or the holes reach oxidizable adsorbed substrate molecules, respectively). Hence, the difference in the conduction band energies of anatase and brookite present in TiO₂-2 impedes the electron mobility, further decreasing the amount of H₂ evolved, see Scheme 1. For the bare TiO₂-2 photocatalyst, the larger surface area compensates the decrease of the charge carrier concentration resulting in an overall efficiency higher than that observed for the other oxides. However, this parameter only has a minor effect on the H₂ evolution in the presence of a co-catalyst.

Conclusions

In this work two different TiO₂ powders were prepared by the sol-gel method followed by thermal treatment in a conventional oven at 400 °C (TiO₂-1) or in a hydrothermal reactor at 200 °C and 12.4 bar (TiO₂-2). The later material exhibited higher surface area than the former, and its XRD pattern evidences the presence of approx. 45% of brookite along with the anatase polymorph. Rietveld refinement indicates a higher distortion on the TiO₂-2 crystalline structure. The photocatalytic activities of the as prepared powders were evaluated using different reactions and were compared to those of the commercial photocatalyst TiO₂-P25. The bare TiO₂-2 exhibited better performance in photocatalytic processes involving an adsorption step, which can be directly related to its higher surface area. When metallic platinum was deposited on the TiO₂ surfaces and the samples were tested for H₂ evolution using methanol as the hole scavenger, the photonic efficiency of TiO₂-1 was approx. 10% higher than that of TiO₂-2. These results were rationalized using nanosecond transient absorption spectroscopy (TAS). It was found that:

1. The electron/hole recombination rates in TiO₂-2 are faster than those in TiO₂-1 due to the more distorted crystalline structure and smaller particle size of the former. This negative aspect is overcompensated by the higher surface area of TiO₂-2 in the absence of any co-photocatalyst.

2. In the presence of platinum as co-catalyst, the photocatalytic efficiency is dominated by the availability of charge carriers at the metal oxide surface.

Thus, the thermal treatment conditions determine two main factors, which influence very strongly the photocatalytic activity of the samples studied here, namely, the crystallinity and the surface area. The high crystallinity, obtained at higher temperatures, is particularly important for the transport of the charge carriers and this seems to be crucial for the production of molecular hydrogen, in which the electrons need to be transported through the oxide particles to the Pt islands.

On the other side, defects (lower crystallinity) are important for the harvesting of the charge carriers after they reach the particle surface, where a higher surface area yields an increase of the reaction rate constants. This behaviour is clearly observed for the TiO₂ particles prepared by the hydrothermal treatment. An important conclusion of this work is that the best photocatalyst for a given photoreaction will not necessarily be the best choice for all photocatalytic processes! This will become particularly critical in the case of the photocatalytic H₂ evolution where the presence of co-catalysts is necessary.
