Constructing water-resistant CH$_3$NH$_3$PbI$_3$ perovskite films via coordination interaction†

Bo Li,a Chengbin Fei,b Kaibo Zheng,ce Xuanhui Qu,a Tõnu Pullerits,c Guozhong Caoad and Jianjun Tian*a

Organic–inorganic halide CH$_3$NH$_3$PbI$_3$ (MAPbI$_3$) perovskite solar cells (PSCs) have attracted intensive attention due to their high power conversion efficiency and low fabrication cost. However, MAPbI$_3$ is known to be very sensitive to humidity, and the intrinsic long-term stability of the MAPbI$_3$ film remains a critical challenge. 2-Aminoethanethiol (2-AET) was used as a ligand to bridge the organic compound (MAI) and inorganic compound (PbI$_2$), which restricted the fast growth of PbI$_2$ to realize the synchronous growth environment of MAI and PbI$_2$ crystals, resulting in the formation of a compact MAPbI$_3$ film with polygonal grains. Due to the compact (PbI$_2$)–2-AET–(MAI) molecule barrier layers in the MAPbI$_3$ structure, the resulting perovskite films showed excellent intrinsic water-resistance, with the MAPbI$_3$ perovskite crystal structure retained for a long time (>10 minutes) after immersion in water. This work makes a step towards obtaining long-term stable MAPbI$_3$ perovskite devices.

Introduction

Methylammonium lead halide organic–inorganic hybrid perovskites, such as CH$_3$NH$_3$PbI$_3$ (MAPbI$_3$), have recently attracted enormous attention for thin-film solar cells due to their high optical absorption coefficient, long free carrier diffusion length, low exciton binding energy and simple low temperature solution-based processing.1–4 Such organic–inorganic hybrid perovskite materials were first made several decades ago, the unique structure of the organic–inorganic perovskites show the potential applications in the electrical and optical fields.5–9 To date, the highest power conversion efficiencies (PCEs) of the perovskite solar cells (PSCs) are above 21%,10 approaching the record efficiencies of monocrystalline silicon-based solar cells (25.6%) and thin film single-crystalline GaAs cells (28.8%).11,12 A serious current deficiency of PSCs is the high sensitivity of MAPbI$_3$ to humidity. The PCE drops nearly 90% under an ambient environment (T = 25 °C, 30–50% humidity) in a few days.13 It has been shown that MAPbI$_3$ can be easily degraded to MAI, PbI$_2$, and HI in a few hours under a high humidity environment.14,15 Moisture in air is considered a key factor causing the decomposition of MAPbI$_3$. Compared to monocrystalline silicon-based solar cells with 20–30 years guaranteed lifetime, the poor stability of PSCs is a crucial barrier to their practical applicability.

Moisture stability has become one of the focus areas of MAPbI$_3$ research. For example, the surfaces of devices or perovskite were covered by p-type metal oxides, hydrophobic materials or insulating polymers to enhance the stability of PSCs under an ambient atmosphere.13,16,17 However, the intrinsic water sensitivity of perovskite films remains an unsolved problem. Recently, it was demonstrated that hydrate intermediate compounds, such as MAPbI$_3$·H$_2$O and (MA)$_4$PbI$_6$·2H$_2$O, were formed at the initial stage of the MAPbI$_3$ decomposition process under controlled humidity conditions, and the degradation reaction could be reversed by drying treatment.18–20 In MAPbI$_3$ perovskite crystals, inorganic PbI$_6$ frameworks and organic MA$^+$ cations are bound together by weak hydrogen and ionic bonds. The migration activation energy for MA$^+$ is approximately 0.84 eV, determined by first-principles calculations.21–23 The strength of hydrogen bonding will be reduced when the perovskite crystal is exposed to H$_2$O or other polar solvents, and MA$^+$ would readily separate from octahedral PbI$_6$, resulting in a rapid decomposition of MAPbI$_3$ and degradation of solar cell performance. It has been suggested that chemical modification between organic cation MA$^+$ and inorganic framework PbI$_6$ in MAPbI$_3$ perovskite can be a way to achieve inherent moisture stability.24–26 For example, butylphosphonic acid 4-ammonium chloride was chosen to crosslink neighboring perovskite grains through hydrogen bonding, leading to increased photovoltaic performance and
moisture stability. 2-Aminoethanethiol (2-AET) has been extensively used as a bidentate chelating agent in coordination chemistry, and shows a high affinity toward binding to Pb$^{2+}$ through the thiolate group. In addition, the ammonium group in 2-AET molecules would bind MAI by hydrogen bonds in the perovskite structure. Therefore, 2-AET can be a great ligand to improve the intrinsic long-term stability of MAPbI$_3$ perovskite.

The present paper reports the fabrication of a novel water-resistant MAPbI$_3$-2-AET perovskite film, with the MAPbI$_3$ crystal structure retained after immersion in water at room temperature (RT) for a long time (>10 minutes). When 2-AET was added into perovskite precursor solution, the thiolate group of 2-AET molecules facilitates strong interaction with PbI$_2$, while the ammonium group can anchor MAI to form PbI$_2$·2-AET·MAI when DMF is removed, providing a homogeneous environment for perovskite crystal nucleation and growth, and leading to uniform perovskite films with excellent crystallinity.

**Experimental section**

**Materials synthesis and perovskite film fabrication**

CH$_3$NH$_3$I (MAI) was prepared by the reported method. Methylamine (33 wt% in methanol) was mixed with hydroiodic acid (HI, 57 wt%) in a molar ratio of 1.2 : 1 at 0 °C. After stirring for 2 h under a N$_2$ atmosphere, the solvent was removed by using a rotary evaporator at 50 °C. Then the obtained powder was washed with ethyl acetate (EA) three times, and then recrystallized in methanol. Finally, the product powder was dried at 60 °C in a vacuum oven for 24 h.

The standard perovskite precursor solutions were prepared by sequentially dissolving the synthesized 159 mg MAI powder and 462 mg PbI$_2$ (Yingkou You Xuan Trade Co., LTD) in 1 mL N$_2$N-dimethylformamide (DMF, 99.8%, Sigma-Aldrich). 2-Aminoethanethiol (2-AET, 95%, Adamas Regent, Ltd.) was added into the perovskite precursor solutions. The precursor solutions were filtered by using a 0.22 μm pore PVDF syringe filter before spin coating.

45 μL standard perovskite precursor solution was spin-coated onto FTO substrates at 3500 rpm for 20 s and 5000 rpm for 10 s, followed by annealing at 100 °C for 10 min. A MAI·2-AET complex was obtained by adding 3 mL ethyl acetate into 1 mL MAI/2-AET (1 : 1 mol%) DMF solution, and the solid complex was filtered and dried at 60 °C in a vacuum oven for 3 h. The MAI/PbI$_2$ complex was obtained by adding 3 mL ethyl acetate into perovskite precursor solution (1 : 1 mol%), and the solid complex was filtered and dried at 60 °C in a vacuum oven for 3 h. The MAI·2-AET·PbI$_2$ complex was obtained by adding 3 mL ethyl acetate into 1 mL 2-AET added perovskite precursor solution (1 : 1 : 1 mol%), and the solid complex was filtered and dried at 60 °C in a vacuum oven for 3 h.

**Characterization**

The IR spectra were measured by using a Bruker Vertex 80v Fourier transform infrared (FTIR) spectrometer. The scanning electron microscopy (SEM) measurements were performed using a cold field emission scanning electron microscope (SU8020, Hitachi). The crystal structure was analyzed by using an X-ray diffractometer (PANalytical, Netherlands) with a monochromatic Cu K$_\alpha$ radiation source (λ = 1.54056 Å). The absorption spectra were recorded using an ultraviolet-visible (UV-vis) spectrophotometer (UV-3600, Shimadzu), and the excitation wavelength was 465 nm. The weight loss was measured on a TGA/DSC instrument (STA 4493F3, NETZSCH) from 30–350 °C with a heating rate of 5 °C min$^{-1}$.

**Results and discussion**

Fig. 1(a) shows the chemical structures of MAI, PbI$_2$ and 2-AET; the 2-AET molecule contains thiolate and ammonium functional groups. In order to completely dissolve PbI$_2$ in DMF solvent, a heating process at 70 °C was usually needed due to the weak interaction of Pb–O coordination bonds between PbI$_2$ and DMF. However, as shown in Fig. S1, PbI$_2$ was quickly dissolved in DMF when 0.2 M 2-AET was added into DMF solution at RT. Fig. 1(b) shows the Fourier transform infrared (FTIR) spectra of pure DMF, PbI$_2$ and PbI$_2$/2-AET DMF solution. The stretching vibration of the C=O bond appears at 1660 cm$^{-1}$ for pure DMF, which is shifted to 1633 cm$^{-1}$ for PbI$_2$ DMF solution, and then the shoulder on the shorter wavenumber side disappears when 2-AET is added into PbI$_2$ solution. Considering that the interaction between Pb–S coordination bonds is stronger than that between Pb–O coordination bonds, the Pb–O coordination bond is replaced by the Pb–S coordination bond when 2-AET is added into PbI$_2$ DMF solution. It demonstrates that the strong interaction of the Pb–S coordination bond between PbI$_2$ and 2-AET is formed in PbI$_2$ DMF solution. Fig. S2† shows FTIR spectra of MAI and MAI/2-AET DMF.
solution, and there is no obvious peak shift, which implies that the interaction between MAI and 2-AET is not formed in DMF solution. In order to further understand the effect of 2-AET on the interaction among PbI₂, MAI and DMF, the solid complexes were extracted from the precursor solution with ethyl acetate (EA) as an extraction agent. Fig. S3(a)† shows the complex without 2-AET dividing into a white upper layer and a yellow bottom layer. The white and yellow products are MAI and PbI₂, respectively. It demonstrates that there is weak interaction among PbI₂, MAI and DMF. No separated layers in the small volume of yellow complexes are found when 2-AET is added into the precursor solution. The complex is fluid, indicating that the strong interaction among PbI₂, MAI and 2-AET is formed after extraction. Fig. S3(b)† shows the Tyndall effect in the complex with the addition of 2-AET under red light illumination, indicating the colloidal characteristic of the complex. Fig. 1(c) and (d) show FTIR spectra of MAI, 2-AET and MAI-2-AET solid complexes. The N–H bending vibration and N–H stretching vibration appear at 1597 cm⁻¹ and 2989 cm⁻¹ for 2-AET, and at 1564 cm⁻¹ and 3099 cm⁻¹ for MAI. However, the N–H bending vibration and N–H stretching vibration of the MAI-2-AET complex shift to 1578 cm⁻¹ and 3059 cm⁻¹, respectively. The N–H vibration frequency of the MAI-2-AET complex is between the 2-AET and MAI, providing evidence for interaction between 2-AET and MAI. Fig. S3(c) and (d)† show X-ray diffraction (XRD) patterns of the complexes with and without the additive of 2-AET. It can be seen that the diffraction peaks could not be indexed to MAI, PbI₂ or MAPbI₃ for the complex without 2-AET, as reported in the literature.⁴¹ XRD patterns of the complex with the addition of 2-AET show several peaks of the new intermediate phase, due to the coordination interaction of 2-AET. The dihedral phase, due to the coordination interaction of 2-AET.

The scanning electron microscopy (SEM) images, XRD patterns and statistical grain size distribution of MAPbI₃-(x)2-AET perovskite films were prepared on FTO substrates, (a) x = 0; (b) x = 0.15 M; (c) x = 0.25 M; (d) x = 0.5 M; (e) x = 0.75 M; (f) x = 1 M. XRD patterns (g) and statistical grain size distribution (h) of MAPbI₃-(x)2-AET perovskite films.

The effect of thermal treatment on the MAPbI₃ perovskite films was investigated. Fig. 3(a)–(f) show SEM images of MAPbI₃-(0.5)2-AET perovskite films heated at 100 °C for different times. There are many pinholes in the MAPbI₃ film without annealing. With the increase of annealing time, perovskite grains grow up and decrease the pinholes. The average grain size of the MAPbI₃ grows up to ~490 nm after annealing at 100 °C for 12 min. So the compact perovskite films are obtained. 2-AET also boosts the growth rate of perovskite crystals during annealing. Fig. S4† shows that the surface
Fig. 3 SEM images of MAPbI$_3$·(0.5)2-AET perovskite films with different thermal annealing times at 100 °C. (a) 0 min; (b) 3 min; (c) 6 min; (d) 9 min; (e) 12 min; (f) 15 min. XRD patterns (g) of MAPbI$_3$·(0.5) 2-AET perovskite films with different thermal annealing times at 100 °C prepared on FTO substrates; selected ranges (h) which contain characteristic diffraction peaks at 13.5°–14.5° and 27°–29°. The diamond indicates the FTO diffraction peaks at 26.52°.

coverage of the MAPbI$_3$·(0.75)2-AET perovskite film is higher than that of the MAPbI$_3$·(0.5)2-AET perovskite film after annealing, indicating that the growth rate of perovskite is accelerated by 2-AET. Fig. 3(g) and (h) show XRD patterns of MAPbI$_3$ perovskite films after thermal annealing at 100 °C for different durations. All annealed perovskite films present increased intensity of diffraction peaks of (110) and (220) crystal planes of the MAPbI$_3$ perovskite structure at 14.1° and 28.45°. There is no detectable peak in the films with increasing the duration of thermal annealing. Table S1† shows the decreased full width at half maximum (FWHM) from 0.22 to 0.11, demonstrating the increased crystallinity of perovskite with increased annealing time. The characteristic peaks of the perovskite films are found to shift to lower angles after annealing for 3 min, and then shift back to higher angles after annealing for 12 min. The reason is ascribed to the effect of 2-AET in the MAPbI$_3$ structure. For MAPbI$_3$·(0.5)2-AET, a part of the free PbI$_2$ and MAI change to MAPbI$_3$ after spin coating. The initially formed film has a poor crystallinity and weak optical absorption of MAPbI$_3$ as shown in Table S1 and Fig. S5.† During the annealing process, the 2-AET additive was gradually pushed out to the boundaries of perovskite grains, which increased the perovskite crystal plane spacing. Subsequently, perovskite grains grew up, which tended to gradually decrease the crystal plane spacing.

Fig. 4 is the schematic illustration of the crystallization process of MAPbI$_3$. The branch-like crystals of MAPbI$_3$ are obtained from standard precursor solution via the asynchronous reaction between PbI$_2$ and MAI. When 2-AET is added into the standard precursor solution, the PbI$_2$-2-AET coordination complex is formed to retard the fast crystallization of PbI$_2$. After spin coating at RT, the PbI$_2$-MAI-DMF-2-AET films are obtained, which provide the synchronous growth environment of MAI and PbI$_2$ crystals. There are three stages to finish the crystallization of perovskite crystals during the annealing process. The remnant DMF gradually evaporates and the MAPbI$_3$·PbI$_2$-MAI-2-AET intermediate phase is formed during the annealing stage (1). Then the intermediate phases obtain enough thermal energy to break the coordination interaction of 2-AET in the annealing stage (2), and the 2-AET additive is concentrated in the grain boundaries of perovskite grains. Finally, together with the growth process of perovskite grains, the 2-AET additive is driven from grain boundaries to the surface of perovskite grains in the stage (3) as shown in Fig. S4(d).†

Fig. 5(a) shows UV-vis absorbance of MAPbI$_3$ perovskite films prepared with different additions of 2-AET. Without 2-AET, the shape of the spectrum shows clear evidence that the film does not provide perfect coverage and consists of areas of high optical density mixed with uncovered parts.39 The perovskite film prepared with 0.15 M 2-AET shows less of this effect. Clearly, the higher concentration of M 2-AET leads to a high-quality film with close to perfect coverage. We point out that the absorption of perovskite films gradually drops when the addition is more than 0.25 M. It should be attributed to the strong coordination interaction of 2-AET in the perovskite film, which forms the complex in the final film, as indicated by the unknown XRD peaks in Fig. S6.† Besides, the decrease of the
absorption of the perovskite films in the 775–800 nm region is caused by the reduced light scattering. The weak light scattering for 2-AET added perovskite films is attributed to the uniform morphology. UV-vis absorption spectra also show a blue shift by ~30 nm from MAPbI$_3$ to MAPbI$_3$ · (0.25)2-AET, which is another evidence for the interaction between PbI$_2$, MAI and 2-AET. The steady-state photoluminescence (PL) spectra in Fig. 5(b) show that the peak of the MAPbI$_3$ · (0.5)2-AET perovskite film is blue shifted by ~30 nm compared to MAPbI$_3$ perovskite.

Fig. 6(a) and (b) show the photographs of MAPbI$_3$ and MAPbI$_3$ · (0.5)2-AET perovskite films immersed in water for different times at RT. SEM images of the films are shown in Fig. S7 and S8.$^8$ It can be seen that the color of MAPbI$_3$ · (0.5)2-AET perovskite films remains dark brown after immersion in water, while MAPbI$_3$ perovskite films undergo a rapid color change from dark brown to yellow. This process has also been recorded in Movie S1.$^7$ XRD patterns of MAPbI$_3$ and MAPbI$_3$ · (0.5)2-AET are shown in Fig. 6(c) and (d). For MAPbI$_3$ perovskite films, PbI$_2$ characteristic peaks at 12.7°, 25.9°, and 34.3° appear after immersion in water for 10 s, and are well indexed to hexagonal PbI$_2$ (JCPDS card no. 07-0235). For MAPbI$_3$ · (0.5)2-AET perovskite films, characteristic peaks at 14.15° and 28.46° of MAPbI$_3$ remain after immersion in water from 10 s to 300 s, without the presence of detectable crystalline PbI$_2$. However, the intensity of the peaks decreases gradually with increasing immersion time from 10 s to 300 s. No visible driffration peak offset nor impurity peaks were observed. Compared to the pristine MAPbI$_3$ · (0.5)2-AET perovskite film, the UV-vis absorption of the film is first enhanced in the wavelength range from 450 nm to 800 nm after immersion in water for 10 s as shown in Fig. 6(e). The possible reason is that the excess 2-AET in the perovskite grain boundary is gradually dissolved in water to form holes in the perovskite film (as shown in Fig. S8†), which enhances the light trapping and the light scattering. Then the absorption is gradually decreased in the short wavelength range with increasing immersion time. However, the absorption edge of PbI$_2$ at ~520 nm as reported in the literature is not found.$^3$ A red shift of the absorption edge from ~770 nm to ~780 nm was also observed for all MAPbI$_3$ · (0.5)2-AET perovskite films after immersion due to the light scattering. As shown in Fig. 6(f), after immersion, the PL peaks also shift 10 nm from 742 nm to 752 nm. After that, the PL curves do not change with increasing immersion time, indicating that the structure of MAPbI$_3$ · (0.5)2-AET is stable in water.

Fig. 7(a) shows XRD patterns of MAPbI$_3$ perovskite films prepared with low addition of 2-AET after immersion in water for 15 s. The degradation rate of MAPbI$_3$ · (x)2-AET increases as the amount of 2-AET addition decreases. As shown in Table S2,$^6$ after immersion in water for 15 s, the diffraction peak of PbI$_2$ at 12.79° shifts to 12.22° when the addition of 2-AET increases from 0 M to 0.3 M. The decreased intensity with increased FWHM of PbI$_2$ characteristic peaks implies that the MAPbI$_3$ degradation process is suppressed by the presence of 2-AET. The schematic diagram of the degradation process of MAPbI$_3$ and possible mechanism of water-resistant MAPbI$_3$ · (x)2-AET perovskite in water are presented in Fig. 7(b) and (c). The absorption edge of PbI$_2$ at ~520 nm as reported in the literature is not found.$^3$ A red shift of the absorption edge from ~770 nm to ~780 nm was also observed for all MAPbI$_3$ · (0.5)2-AET perovskite films after immersion due to the light scattering. As shown in Fig. 6(f), after immersion, the PL peaks also shift 10 nm from 742 nm to 752 nm. After that, the PL curves do not change with increasing immersion time, indicating that the structure of MAPbI$_3$ · (0.5)2-AET is stable in water.

Fig. 7(a) shows XRD patterns of MAPbI$_3$ perovskite films prepared with low addition of 2-AET after immersion in water for 15 s. The degradation rate of MAPbI$_3$ · (x)2-AET increases as the amount of 2-AET addition decreases. As shown in Table S2,$^6$ after immersion in water for 15 s, the diffraction peak of PbI$_2$ at 12.79° shifts to 12.22° when the addition of 2-AET increases from 0 M to 0.3 M. The decreased intensity with increased FWHM of PbI$_2$ characteristic peaks implies that the MAPbI$_3$ degradation process is suppressed by the presence of 2-AET. The schematic diagram of the degradation process of MAPbI$_3$ and possible mechanism of water-resistant MAPbI$_3$ · (x)2-AET perovskite in water are presented in Fig. 7(b) and (c). The absorption edge of PbI$_2$ at ~520 nm as reported in the literature is not found.$^3$ A red shift of the absorption edge from ~770 nm to ~780 nm was also observed for all MAPbI$_3$ · (0.5)2-AET perovskite films after immersion due to the light scattering. As shown in Fig. 6(f), after immersion, the PL peaks also shift 10 nm from 742 nm to 752 nm. After that, the PL curves do not change with increasing immersion time, indicating that the structure of MAPbI$_3$ · (0.5)2-AET is stable in water.

Fig. 7(a) shows XRD patterns of MAPbI$_3$ perovskite films prepared with low addition of 2-AET after immersion in water for 15 s. The degradation rate of MAPbI$_3$ · (x)2-AET increases as the amount of 2-AET addition decreases. As shown in Table S2,$^6$ after immersion in water for 15 s, the diffraction peak of PbI$_2$ at 12.79° shifts to 12.22° when the addition of 2-AET increases from 0 M to 0.3 M. The decreased intensity with increased FWHM of PbI$_2$ characteristic peaks implies that the MAPbI$_3$ degradation process is suppressed by the presence of 2-AET. The schematic diagram of the degradation process of MAPbI$_3$ and possible mechanism of water-resistant MAPbI$_3$ · (x)2-AET perovskite in water are presented in Fig. 7(b) and (c). The absorption edge of PbI$_2$ at ~520 nm as reported in the literature is not found.$^3$ A red shift of the absorption edge from ~770 nm to ~780 nm was also observed for all MAPbI$_3$ · (0.5)2-AET perovskite films after immersion due to the light scattering. As shown in Fig. 6(f), after immersion, the PL peaks also shift 10 nm from 742 nm to 752 nm. After that, the PL curves do not change with increasing immersion time, indicating that the structure of MAPbI$_3$ · (0.5)2-AET is stable in water.

Fig. 7(a) shows XRD patterns of MAPbI$_3$ perovskite films prepared with low addition of 2-AET after immersion in water for 15 s. The degradation rate of MAPbI$_3$ · (x)2-AET increases as the amount of 2-AET addition decreases. As shown in Table S2,$^6$ after immersion in water for 15 s, the diffraction peak of PbI$_2$ at 12.79° shifts to 12.22° when the addition of 2-AET increases from 0 M to 0.3 M. The decreased intensity with increased FWHM of PbI$_2$ characteristic peaks implies that the MAPbI$_3$ degradation process is suppressed by the presence of 2-AET. The schematic diagram of the degradation process of MAPbI$_3$ and possible mechanism of water-resistant MAPbI$_3$ · (x)2-AET perovskite in water are presented in Fig. 7(b) and (c).
MAPbI$_3$ film prepared without the addition of 2-AET degrades rapidly to hexagonal PbI$_2$. However, in the case of the MAPbI$_3$ film prepared with the addition of 2-AET, the distribution of 2-AET in perovskite grain boundaries forms compact (PbI$_2$)-2-AET-(MAI) molecule barrier layers, which can effectively prevent H$_2$O from penetrating into MAPbI$_3$ crystals. As a result, although 2-AET dissolves easily in water, MAPbI$_3$-2-AET perovskite shows excellent water-resistance due to the coordination interaction between 2-AET and MAPbI$_3$ by hydrogen bonds.

Fig. 8 shows differential scanning calorimetry/thermogravimetric analysis (DSC/TGA) curves of MAPbI$_3$ and MAPbI$_3$-(0.75) 2-AET. The color of MAPbI$_3$-(0.75) 2-AET powders changed from yellow to black after the TGA/DSC measurement, while the color of MAPbI$_3$ still remained black. The weight loss for both perovskite powders is approximately the same, 4% from RT to 125 °C, which is attributed to the evaporation of physically adsorbed H$_2$O or DMF. For MAPbI$_3$ powder, the TGA curve stepwise decreases with an obvious endothermic peak at ~125 °C, likely due to the removal of combined water. In the case of MAPbI$_3$-(0.75)2-AET powder, the mass consecutively drops with an increasing temperature from 30 °C to 125 °C, and there is no endothermic peak at ~125 °C, so the weight loss is related to evaporation of DMF. This may imply that the reported hydrate intermediate compounds (MAPbI$_3$·H$_2$O or (MAI)$_2$PbI$_2$·2H$_2$O) are not formed in MAPbI$_3$-(0.75)2-AET powder. No visible weight loss is observed between 125 °C and 225 °C for MAPbI$_3$ powder, which is consistent with other reports. The weight loss is 6.64% between 150 °C and 225 °C for MAPbI$_3$-(0.75)2-AET powder, which is close to the amount of (8.54%) 2-AET added into precursor solution. However, as shown in Fig. S9, for pure 2-AET powder, the weight loss is only 6.27%. In addition, the DSC curve shows obvious endothermic peaks at 200–225 °C, so the poor thermal stability should be attributed to a series of reactions between MAPbI$_3$ and 2-AET, and the reaction products will be evaporated from the perovskite powder.

**Conclusions**

Excellent and intrinsic water-resistant MAPbI$_3$-(x)2-AET perovskite films have been grown and demonstrated. 2-AET is a ligand with strong coordination interactions not only observed in the perovskite precursor solutions, but also in the resulting perovskite crystal structure. The colloidal PbI$_2$-2-AET-MAI complexes have a great influence on the nucleation and growth process, and the synchronous growth of MAI and PbI$_2$ crystals is realized during a one-step spin coating process. MAPbI$_3$-(x)2-AET during the thermal annealing process leads to the growth of compact perovskite films with significant preferential orientation of (110) and (220) planes and enhanced crystallinity. Due to the compact (PbI$_2$)–2-AET-(MAI) molecule barrier layers in the MAPbI$_3$ structure, the perovskite films show excellent intrinsic water-resistance, with the MAPbI$_3$ perovskite crystal structure retained after immersion in water for a long time (>10 minutes).
