A self-assembled, multicomponent water oxidation device†

Rita Tóth,a Roché M. Walliser,b Niamh S. Murray,b Debajeet K. Bora,a Artur Braun,a Guiseppino Fortunato,c Catherine E. Housecroftb and Edwin C. Constable*a

Langmuir–Blodgett (LB) and drop-cast (DC) films prepared from [Ru(1)3][PF6]2 and Co4POM (1 = 4,4′-bis(nonyl)-2,2′-bipyridine, Co4POM = K10[Co4(H2O)2(VW9O34)2]) have been evaluated as water oxidation catalysts and their electrocatalytic performances are reported; DC films evolve more O2 per unit area than LB films and the catalyst is stable on an FTO surface for ≈ 500–600 minutes.

Developing clean, renewable energy sources is one of the greatest challenges facing mankind,1 and a promising approach is that of artificial photosynthesis.2 Inspired by Nature and an understanding of the mechanisms exhibited by photosystems I and II many groups are investigating the photoelectrochemical or photocatalytic splitting of water into H2 and O2.3 Of the two half-reactions of water splitting, oxidation to O2 is more challenging involving four electrons, four protons, two H2O molecules and the final formation of an O–O bond. High activation energies and slow kinetics motivates the development of water oxidation catalysts (WOC) which are efficient at minimal overpotential, hydrolytically and oxidatively stable and composed of inexpensive, earth-abundant materials.4 Recently carbon-free, molecular polyoxometalate (POM) WOCs have been incorporated in both homogeneous and heterogeneous systems.5 A polyoxometalate K10[Co4(H2O)2(PW9O34)2] [Co4POM] and a more efficient vanadium-containing polyoxometalate [Co4(H2O)2(VW9O34)2]10, function as effective homogeneous WOCs when combined with an in situ generated [Ru(bpy)3]3+ oxidant.6 A solid–aqueous interface, can both control the organization of the components and enhance the overall efficacy.7–12

We have recently prepared films from [Ru(1)3][PF6]2 (see Scheme 1 for ligand 1) and Co4POM on mica using the LB technique for use as a WOC in an electrochemical water splitting cell.13 We now compare the electrocatalytic performance of LB layers with layer-by-layer drop-cast (DC) films of the same components on fluorine doped tin oxide (FTO) coated glass slides as a conductive substrate.

LB films were self-assembled on the substrates by the vertical lifting method, with withdrawal and immersion of the substrate through the film.13 The substrate was allowed to dry in air after each withdrawal for 5 minutes prior to the next immersion/withdrawal cycle. The films were prepared with 50 dipping cycles. Details of the preparation of the LB and DC films are given in the ESI.†

SEM-FIB images of LB films before and after electrocatalytic treatment (Fig. S1 versus S2, ESI†) show that the surface of a multiple-layer LB film is smoother than the FTO surface (Fig. S3, ESI†) but is still rough. This surface structure of the electrodes is essential for the catalytic activity. The surface of the DC films is more uneven (Fig. S4, ESI†), with the film thickness ranging between 10 nm and a few microns.

To assess the WOC performances of the LB and DC films, along with films of the individual drop-cast components ([Ru(1)3][PF6]2 and Co4POM), cyclic voltammetry (CV) measurements were performed at pH 7.6 in phosphate buffer saline (PBS) solution in a three-electrode system (ESI†). Fig. 1 shows that the catalytic activity of the bare FTO-coated glass and the
respectively), however, the current onsets at /C0 2.16 mA cm\(^{-2}\) for oxidation at pH 7.6 (0.59 V vs. Ag/AgCl) at least 0.52 V over the thermodynamic potential for water oxidation vs. Ag/AgCl (and +1.0 V vs. Ag/AgCl, see Fig. S7, ESI†) since the applied potentials are higher than their water oxidation onset potential. The LB film performs better at +1.3 V than at +1.0 V bias potential due to its higher onset potential of +1.23 V (Fig. S7, ESI†).

The long-term stability of the systems was confirmed by chronoamperometric measurements. A bias of +1.3 V (vs. Ag/AgCl) was applied for >600 minutes and the current was recorded under working conditions (Fig. 3). After the initial drop, the current was relatively stable. The spikes on the curves are due to bubble formation, and desorption from the surface of the film. The results are similar to those for a study related to a spinel mixed oxide electrode.\(^{14}\) On the smoother surface of the LB films, fewer bubbles form than on the rough surface of the DC films. The height of the spikes scales with the observed current density.

We compared the amount of evolved O\(_2\) measured by gas chromatography with the theoretical number of moles of O\(_2\) obtained from the current density data (shown in Fig. 3) applying Faraday’s law (integrated current/4F) (Fig. 4).\(^{15}\) The amount of O\(_2\) determined from the GC experiment is around six times lower than that calculated for DC films and about one third of the theoretical value for LB films at 600 minutes. This can be attributed to the dissolution of O\(_2\) in the relatively large volume of electrolyte (59 cm\(^3\)) compared to the 1 cm\(^2\) area of the electrode containing ~3.5 nmol catalyst. The measured current density may also include parasitic side reactions. It is evident that the amount of catalyst material on the FTO substrate is lower after anodizing the electrodes for a significant period of time than in the initial DC and LB films (Fig. S8, ESI†). Initially, the electrodes show structures with a cracked pattern similar to the LB and DC films or [Ru(1)_3][PF_6]_2, the oxygen amount in the headspace steadily increased during the 1100 minutes for which the reaction was monitored above the Co_4POM film. The DC films evolved slightly more O\(_2\) per area than the LB films. However, the thickness of the DC films is greater and the surface was more uneven than the layers prepared by the LB technique (Fig. S4 and S8, ESI†).

Under a lower applied bias of +1 V vs. Ag/AgCl the DC, Co_4POM and [Ru(1)_3][PF_6]_2 films evolve approximately the same amount of O\(_2\) as at +1.3 V vs. Ag/AgCl bias (Fig. S7, ESI†). The long-term stability of the systems was confirmed by chronoamperometric measurements. A bias of +1.3 V (vs. Ag/AgCl) was applied for >600 minutes and the current was recorded under working conditions (Fig. 3). After the initial drop, the current was relatively stable. The spikes on the curves are due to bubble formation, and desorption from the surface of the film. The results are similar to those for a study related to a spinel mixed oxide electrode.\(^{14}\) On the smoother surface of the LB films, fewer bubbles form than on the rough surface of DC films. The height of the spikes scales with the observed current density.

We compared the amount of evolved O\(_2\) measured by gas chromatography with the theoretical number of moles of O\(_2\) obtained from the current density data (shown in Fig. 3) applying Faraday’s law (integrated current/4F) (Fig. 4).\(^{15}\) The amount of O\(_2\) determined from the GC experiment is around six times lower than that calculated for DC films and about one third of the theoretical value for LB films at 600 minutes. to the Co–Pi catalyst surface reported by Nocera.\textsuperscript{7} The post-electrochemical treated films show a very small amount of catalyst and the bare FTO surface is clearly visible in scanning electron microscopy (SEM) images (Fig. S8, ESI†) taken after 1000 min operation. However, the film thickness and surface structure remained the same after, (Fig. S1 and S2, ESI†) and the films were stable during, 1 h of catalytic activity.

The estimated amounts of Co\textsubscript{4}POM and [Ru(1)\textsubscript{3}][PF\textsubscript{6}]	extsubscript{2} in the LB film are \(\leq 3.5\) nmol cm\(^{-2}\) and \(\leq 1.5\) nmol cm\(^{-2}\), respectively, and 1370 nmol cm\(^{-2}\) for the complexes in the DC film. From 1 cm\(^2\) LB and DC films, 34 and 43 nmol O\textsubscript{2} evolved, respectively, in 600 minutes as measured by gas chromatography. The theoretical values for the same time interval, which were calculated from the current density data, are 94 and 298 nmol for 1 cm\(^2\) LB and DC films. Both measured and calculated values far exceed the amount that the stoichiometric reaction with water would give.

The calculated turnover numbers and turnover frequencies for the LB and DC films are the following: TON = \(n_0/h_{\text{catalyst}}\) = 23 mol O\textsubscript{2} per mol [Ru(1)\textsubscript{3}][PF\textsubscript{6}]	extsubscript{2}, or 10 mol O\textsubscript{2} per mol Co\textsubscript{4}POM in 600 min for 1 cm\(^2\) LB films, and 0.03 mol O\textsubscript{2} per mol complex on 1 cm\(^2\) DC films; TOF = \(n_0/h_{\text{catalyst}}\) = 0.0006 mol O\textsubscript{2} per s per mol [Ru(1)\textsubscript{3}][PF\textsubscript{6}]	extsubscript{2}, or 0.00028 mol O\textsubscript{2} per s per mol Co\textsubscript{4}POM for 1 cm\(^2\) LB films, and 0.00005 mol O\textsubscript{2} per s per mol complex on 1 cm\(^2\) DC films. The TOF is lower than the value reported\textsuperscript{6} for a similar WOC system used as a homogeneous catalyst (\(\geq 5\) s\(^{-1}\)). In contrast to homogeneous catalysis where all molecules contribute to the catalytic activity, heterogeneous catalysis only occurs at selected surface sites. This is a likely reason for the lower TOF. Our TOF value is comparable to that of 0.0007 s\(^{-1}\) calculated for the WO\textsubscript{C} formed \textit{in situ} on the surface of an indium tin oxide electrode from Co\textsuperscript{3+} containing neutral aqueous phosphate solution.\textsuperscript{7} Although a TOF value was not reported in Nocera’s work, it was possible to calculate\textsuperscript{7} the lower limit since the amount of catalyst was given.

Powders and films of [Ru(1)\textsubscript{3}][PF\textsubscript{6}]	extsubscript{2} and Co\textsubscript{4}POM were studied by X-ray diffraction (XRD) to examine how they changed during film preparation. It is clear that the [Ru(1)\textsubscript{3}][PF\textsubscript{6}]	extsubscript{2} powder and film contain ruthenium(II) metaphosphate, Ru(PO\textsubscript{3})\textsubscript{2}, which has a triclinic structure and is built from Ru\textsuperscript{3+} ions and infinite [PO\textsubscript{3}\textsubscript{−}]\textsubscript{6} chains.\textsuperscript{16} The Co\textsubscript{4}POM powder and film contain K\textsubscript{3}CoWO\textsubscript{4}(PO\textsubscript{3})\textsubscript{2}, which is a possible building block of the [Co\textsubscript{4}(H\textsubscript{2}O)\textsubscript{6}(PW\textsubscript{9}O\textsubscript{34})\textsubscript{2}]\textsuperscript{10−} polyoxometalate. Interestingly, in the DC film the mixture of [Ru(1)\textsubscript{3}][PF\textsubscript{6}]	extsubscript{2} and Co\textsubscript{4}POM, a third kind of peak appears which is a convolution of the Ru(PO\textsubscript{3})\textsubscript{2} and K\textsubscript{3}CoWO\textsubscript{4}(PO\textsubscript{3})\textsubscript{2} peaks. This suggests an interaction between the ruthenium complex and Co\textsubscript{4}POM occurs during film preparation. The XRD results also reveal the presence of CoO\textsubscript{1.29} both in the DC and LB films. The XRD patterns of the films before and after electrocatalytic activity were also compared. Similar to the SEM images, the XRD results confirm the desorption of most of the films from the substrate during 1000 minutes catalytic activity. The occurrence of Co\textsubscript{2}p, W4f, Ru3p and N1s peaks in X-ray photoelectron spectroscopy (XPS) survey scans confirm the presence of both Co\textsubscript{4}POM and [Ru(1)\textsubscript{3}][PF\textsubscript{6}]	extsubscript{2} in the films. For detailed XRD and XPS analysis see Fig. S9–S13 and Table S1 (ESI†) and accompanying text.

The DC films evolve about 10 nmol cm\(^{-2}\) more O\textsubscript{2} than the LB films at +1.3 V applied bias potential. The onset potential for DC [Ru(1)\textsubscript{3}][PF\textsubscript{6}]	extsubscript{2}/Co\textsubscript{4}POM and DC Co\textsubscript{4}POM films is \(\approx 0.1\) V lower than for the LB [Ru(1)\textsubscript{3}][PF\textsubscript{6}]	extsubscript{2}/Co\textsubscript{4}POM films, possibly arising from the larger surface area with more catalytic sites on the island-like structure of the DC film shown on the SEM images (Fig. S8, ESI†). Although the Co\textsubscript{4}POM evolves less O\textsubscript{2} during the first 500–700 minutes than the LB and DC [Ru(1)\textsubscript{3}][PF\textsubscript{6}]	extsubscript{2}/Co\textsubscript{4}POM system, it continues to produce a linearly increasing amount of O\textsubscript{2} after the other two films have reached saturation. As significantly less Co\textsubscript{4}POM was observed on the electrode after electrolysis than before electrolysis, it appears that Co\textsubscript{4}POM worked in part as a homogeneous catalyst and also partially decomposed to CoO\textsubscript{x}, which is an effective WOC catalyst. An ongoing debate concerns the stability of Co\textsubscript{4}POM and whether the polyoxometalate or CoO\textsubscript{x} is the true catalyst in the homogeneous systems. The reaction conditions, (pH, bias potential, buffer and the concentration of the catalyst) have a huge impact on the stability of Co\textsubscript{4}POM.\textsuperscript{17} In the homogeneous system, not only water molecules but also the organic ligand of the Ru complex are oxidized, furthermore precipitates form from the Co\textsubscript{4}POM and Ru complex and Co\textsubscript{4}POM decomposes in phosphate buffer at neutral and basic pH values where the POM catalyst is most active. When the catalyst is immobilized on an electrode surface, desorption of the catalyst and oxidant/photosensitizer is also an issue.\textsuperscript{18} All of these parameters affect the stability of our catalytic system and contribute to the cessation of catalytic activity after 600 minutes. The detailed investigation of the stability of the system was not the scope of this study.

In conclusion, we have prepared two kinds of water oxidizing electrodes: (i) alternating, smooth Langmuir–Blodgett monolayers of abundant, inorganic Co\textsubscript{4}POM catalyst and [Ru(1)\textsubscript{3}][PF\textsubscript{6}]	extsubscript{2} oxidant and (ii) also alternating, uneven drop cast layers of the two above mentioned components, both on FTO substrate. We have found that both electrodes are efficient oxygen evolving anodes at pH 8 and the DC film evolves slightly more O\textsubscript{2} per geometrical area due
to its higher surface area. The catalyst is stable on the FTO surface for about 500–600 minutes. In long term operation, the drop cast Co₄POM catalyst on its own evolves more O₂ than the [Ru(1)(][PF₆]²⁻)/Co₄POM combined layers, most likely because it is not stable on the FTO surface and works as a homogeneous catalyst in the electrolyte. The turnover frequency of the LB and DC electrodes is lower than that of the homogeneous system of the same components reported by Hill, however, it is higher than the turnover frequency reported for Co₄POM forming in situ on the surface of indium tin oxide electrode. Potentially, the stability of the system could be enhanced in the future by improving the binding of the catalyst system to the substrate and the components to each other, avoiding phosphate buffer and using for example borate buffer and using as low as possible bias potential. Organic oxidant/photosensitiser should also be avoided but a viable inorganic component has not yet been developed.

We thank the Swiss National Science Foundation (http://p3.snf.ch/project-137868) R’Equip. (http://p3.snf.ch/project-121306), the European Research Council (Advanced Grant 267816 LiLo) and the University of Basel for financial support. Financial support for D. K. B. from the Swiss National Science Foundation (NanoTera project SHINE, 20NA21-145936) and for R. T. from the Marie Heim Vögtlin Foundation (http://p3.snf.ch/project-139698) are gratefully acknowledged. We thank Hongjin Lv (Emory University) for providing the Co₄POM complex. The sealed electrochemical cell was designed by K. Gajda-Schrantz and H. Altorfer at Empa.
