A switchable dual organocatalytic system and the enantioselective total synthesis of the quadrane sesquiterpene suberosanone†

Yajun Ren,^a Marc Presset,^{‡a} Jeremy Godemert,^a Nicolas Vanthuyne,^a
Jean-Valère Naubron,^b Michel Giorgi,^b Jean Rodriguez*^a and Yoann Coquerel*^a

The combination of aminocatalysis with N-heterocyclic carbene catalysis has been extended to a switchable dual catalytic system, which allowed a direct enantioselective entry to bridged bicyclo[3.2.1] ring systems and the total synthesis of the natural product (1*R*)-suberosanone.

Quadrans form a small class of cytotoxic sesquiterpene natural products, originated either from terrestrial or marine organisms, and belonging to the larger group of polyquinanes.¹ It is worth mentioning that natural products have in the past and continue to play a crucial role in the discovery of drugs for the benefit of mankind.² Although the first known naturally occurring quadrane, namely quadron, was isolated back in 1978, despite considerable synthetic efforts, no enantioselective total synthesis of a quadrane natural product has been reported.^{1,3} Actually, most quadrans are of unknown absolute configuration even though they are all presumed to exist naturally as their (1*R*) enantiomers.^{1,4} The absolute configuration of the quadrane suberosanone (1) was recently assigned as (1*S*) by chemical synthesis.⁵ Intrigued by this oddity, and motivated by the development of an original enantioselective organocatalytic method for the synthesis of functionalized bridged bicyclo[3.2.1]octane compounds⁶ applicable to the synthesis of most, if not all, quadrans, we embarked on the total synthesis of (1*R*)-suberosanone (1). It was devised that (1*R*)-1 would be accessible in a few steps starting from the bicyclo[3.2.1]octane (1*R*)-2, which we planned to prepare using a yet-to-discover enantioselective dual organocatalytic Michael/aldolization sequence from the β-ketoester 4 and crotonaldehyde (5a, Scheme 1).⁷

Scheme 1 Retrosynthetic analysis for suberosanone, and planned enantioselective dual organocatalytic Michael/aldol sequence. BB = Brønsted base activation. IM = iminium activation.

Based on the accumulated knowledge on enantioselective organocatalytic Michael additions with 1,3-dicarbonyl compounds, we were confident that highly enantio-enriched Michael adduct intermediates of type 3 could be obtained from pronucleophiles of type 4 under iminium activation.⁸ An additional Brønsted base would then be required to operate the ring-closing aldolization step. Although enticing, this idea raised some challenging issues: (i) iminium activation is a reversible process;⁸ (ii) previous work on the synthesis of bridged ring systems of type 2 *via* Brønsted base-promoted Michael/aldolization sequences in the racemic series established that these reactions are fully reversible when performed with common Brønsted bases (*e.g.* DBU);⁹ (iii) Michael adducts of type 3 readily racemize, precluding their isolation in high enantiopurity under standard conditions;^{10a} and (iv) intermediates of type 3 amenable to applications to the total synthesis of quadrans exhibit a gem-dimethyl group in the vicinity of the aldolization site, which should both notably slow down the aldolization step and favor Brønsted base-catalyzed retro-Michael/Michael processes leading to racemization. Recently, it was discovered that hindered imidazolylidene N-heterocyclic carbenes (NHCs) are potent Brønsted bases capable of catalyzing Michael/aldolization sequences, but with little tendency for reversibility.¹¹ It was hypothesized that the planned enantioselective Michael/aldolization sequence leading to (1*R*)-2 could be achieved using a sequential combination of the aminocatalyst I and the NHC catalyst II in a one-pot dual catalytic process.¹²

In order to test this idea, the prototypical reactions of the β-ketoesters 4a and 4d with crotonaldehyde (5a) were examined

under various dual catalytic conditions (Table 1). Because all the four possible diastereomers of **2a,d** can be expected in different proportions, the crude reaction products were directly oxidized into the corresponding diketones **6a,d** to simplify analysis. The benchmark result was obtained by the sequential combination of catalyst **I** and DBU, which afforded product **6a** with low enantioselectivity due to DBU-catalyzed racemization processes (entry 1). In contrast, it was found that the sequential addition of catalysts **I** and **II** to solutions of **4a** and **5a** produced, after oxidation, the diketone **6a** in generally good yields and stereoselectivities (entries 2–5). The reaction in dichloromethane (entry 2) gave the best enantioselectivity but a low yield, which could be improved in toluene (entry 3). Alternatively, methanol afforded comparable results in a somewhat accelerated reaction (entry 4), while substituting catalyst **I** by the so-called MacMillan's second generation catalyst¹³ gave **6a** in lower yield and enantioselectivity (entry 5). Other dual organocatalytic systems combining an aminocatalyst with a NHC have been reported in the past few years.¹⁴ Among these, Lathrop and Rovis reported an elegant enantioselective Michael/crossed benzoin sequence from the methyl ester analog of **4a** (the precursor of **6c**, see Fig. 1) and aldehyde **5a** using a combination of catalyst **I** and an achiral triazolylidene NHC catalyst to give a fused bicyclo[3.3.0]octane product.^{10,15} Remarkably, and in sharp contrast to the Lathrop and Rovis study, no fused bicyclo[3.3.0]octane products could be detected in the intermediate crude products **2**, illustrating the perfectly switchable nature of the overall dual organocatalytic transformation as a function of the NHC catalyst employed (triazolylidene vs. hindered imidazolylidene).¹⁶ More generally, this represents the first described switchable dual catalytic enantioselective transformation. Stimulated by these results, we then moved to the more

Fig. 1 Scope of the dual organocatalytic reaction. See the ESI† for full experimental details.

challenging substrate **4d** (entries 6–9). In that case, the reaction was only found possible in methanol and afforded product **6d** with moderate enantioselectivity under the conditions previously used for **6a** (compare entries 4 and 7). It was hypothesized that reducing the amount of free NHC **II** in solution would limit the undesired competitive NHC-catalyzed Michael addition leading to racemization. Indeed, a reaction conducted with only 3 mol% of **II** allowed the isolation of product **6d** with a significantly better enantioselectivity (entry 8). Following the same idea, masking the NHC as its azolium salt *in situ* should allow maintaining of only a tiny amount of the free NHC **II** in solution. In practice, it was found that adding acetic acid together with **II** after the Michael addition step afforded the product **6d** in good yield and improved enantioselectivity, at the expense of prolonged reaction time (entry 9).¹⁷ The reaction was then examined using other cyclic α -activated ketones and α,β -unsaturated aldehydes, which afforded the bridged bicyclic products **6a–m** with good to excellent yields and stereoselectivities (Fig. 1). The enhancement of diastereoselectivity observed in many cases was expected and ensued from the decomposition of the minor diastereomers of **2** having equatorial substituents by methanol-mediated retro-Dieckmann fragmentation processes (see the ESI†).^{9,18} In a few cases, the MacMillan's second generation catalyst¹³ performed better than its counterpart **I** (e.g. for **6i** and **6j**, see the ESI†). The determination of the absolute configurations in products **6a–m** is based on previous work,^{8,10} and was confirmed by derivatization, X-ray diffraction analysis, and full chiroptical characterization of the targeted natural product (see below and the ESI†).

With the new enantioselective methodological tool described above in hand, the total synthesis started with a scale up study, which afforded **2d** as a mixture of four diastereomers in 90% yield on a 12 gram scale (Scheme 2). The oxidation of an analytic sample of **2d** delivered the diketone **6d** with similar yield and stereoselectivities when compared to the methodological scale series (2:1 dr, 8:1 er, compare with Table 1, entry 7).¹⁹ The Barton–McCombie deoxygenation of **2d** afforded the key intermediate **7** in 85% yield (2:1 dr, 9.2 g batch), which was later in

Entry	Solvent	Conditions	Yield ^a	dr ^b	er ^c
1 ^d	MeOH	2 days	6a , 77%	3:1	5:1
2	CH ₂ Cl ₂	2 days	6a , 28%	4:1	27:1
3	Toluene	2 days	6a , 71%	4:1	26:1
4	MeOH	1 day	6a , 75%	4:1	18:1
5 ^e	MeOH	1 day	6a , 60%	4:1	10:1
6	Toluene	2 days	6d , <5%	—	—
7	MeOH	1 day	6d , 80%	2:1	8:1
8 ^f	MeOH	3 days	6d , 90%	2:1	12:1
9	MeOH	AcOH (20 mol%), 4 days	6d , 90%	2:1	16:1

^a For the isolated pure product (0.5 mmol scale reactions). ^b Determined by NMR analysis of the crude product. ^c For the major diastereomer, determined by HPLC. ^d Reaction performed with DBU instead of **II**. ^e Reaction performed with so-called MacMillan's second generation catalyst instead of **I**. ^f Reaction performed with only 3 mol% of **II**.

Scheme 2 Total synthesis of (1R)-suberosanone (1).

the synthesis confirmed to maintain the 8:1 er of the major diastereomer. The initially planned strategy to convert 7 into the natural product 1 and its congeners was relied on the early olefination of the ketone carbonyl group at C2. Regrettably, we soon had to face the problem that the C2 carbonyl group and the corresponding olefins were extremely difficult to react, and when possible, with the desired diastereoselectivity. These difficulties were attributed to severe cumulative steric effects at C2 caused by its neopentyl position, a 1,3-diaxial interaction on the β -face, a gem-dimethyl group on the α -face, and a conformational rigidity. Overall, the chemical transformation of the key intermediate 7 revealed to be much more difficult than anticipated, but also more exciting. Ultimately, we had to proceed through the protection of the ketone group at C2 in two steps for the reasons given above, which actually turned out beneficial for the issue of the total synthesis. The diastereoselective reduction of the ketone group in 7 (2:1 dr) with sodium borohydride afforded the corresponding mixture of diastereomers **8a** and **8b** (77%, 2:1 dr). Following the serendipitous observation that **8a** and **8b** could be kinetically differentiated in etherification reactions, they were separated by the selective benzoylation of the minor diastereomer **8b** having an equatorial methyl group to give **9b** using NaH/BrBn. A single recrystallization of the remaining diastereomerically pure alcohol **8a** (>50:1 dr, 8:1 er) afforded enantiopure crystalline **8a** (52%, >199:1 er) suitable for X-ray diffraction analysis, which confirmed both its relative and absolute configurations to be as depicted (see the ESI†).²⁰ The alcohol **8a** was then converted into its benzyl ether **9a**

using KH/BrBn, and the subsequent Arndt–Eistert homologation²¹ afforded the carboxylic acid **11** via the methyldiazoketone **10**. The carboxylic moiety in **11** was transformed into the corresponding methyl ketone with methyl lithium, and the C2 carbonyl group was restored to afford the desired diketone **12**. From **12**, the endgame strategy was largely inspired by previous work on the total syntheses of quadranes.¹ It was found that *t*-BuOK promoted an efficient ring-closing aldolization/dehydration sequence from **12** to give the corresponding cyclopentenone **13**, the diastereoselective α -methylation of which under standard conditions furnished the tricyclic late intermediate **14**. Finally, the diastereoselective hydrogenation of the double bond in **14** afforded quantitatively the target product (1R)-suberosanone (**1**). The enantioselective synthesis of **12** also constitutes a formal enantioselective total synthesis of the related quadrane natural product (1R)-suberosenone.⁵

With synthetic samples of (1R)-**1** in hand, we tackled the issue of the determination of the absolute configuration of naturally occurring **1**. To do so, we performed a full chiroptical characterization of (1R)-**1**, including optical rotatory dispersion (ORD), electronic circular dichroism (ECD) and vibrational circular dichroism (VCD) studies (see the ESI†). The $[\alpha]_D$ of the natural sample of **1** extracted from the gorgonian *Isis hippuris* was measured at $[\alpha]_D^{25} = -60$ ($c = 0.1$, CHCl₃),²² while the synthetic sample of (1R)-**1** prepared by Dumas and co-workers showed $[\alpha]_D^{19} = +53.4$ ($c = 0.1$, CHCl₃).⁵ On that basis, the absolute configuration of naturally occurring **1** was assigned as (1S). The measurement of the optical rotation of our synthetic samples of (1R)-**1** (er > 199:1) afforded the following values: $[\alpha]_D^{25} = +20$ ($c = 0.1$, CHCl₃), $[\alpha]_D^{15} = +20$ ($c = 0.1$, CHCl₃), and $[\alpha]_D^{25} = +11$ ($c = 0.1$, EtOH).²³ Additionally, Stephens and co-workers predicted $[\alpha]_D = -20.6$ (gas phase) for (1R)-**1** by DFT calculations.⁴ A puzzling situation! Although we have no sound explanation for these discrepancies in the $[\alpha]_D$ values,²⁴ some clues came from the comparison of the ORD of our synthetic (1R)-**1** with the predicted ORD (DFT) for (1R)-**1**, as well as with the experimental and theoretical ORDs of (1R)-quadrene (Fig. 2). On the basis of similar shapes of ORDs, and in line with Stephens and co-workers' intuition on the occurrence of a single absolute stereogenicity in quadranes biosynthesis, the absolute configuration of naturally occurring **1** is likely to be (1R). However, a clear-cut answer to this question can only arise from additional chiroptical characterization of the naturally occurring material.

In summary, a remarkable divergence was identified in dual organocatalytic transformations combining a secondary amine and a NHC catalyst, the NHC operating as the reactivity switch. A practical enantioselective method for the synthesis of functionalized bicyclo[3.*n*.1] derivatives resulted. This original switchable bicatalytic transformation opens up avenues for the conceptualization of switchable multicatalytic transformations. The dual catalytic method described herein was initially elaborated to provide the first enantioselective route to the cytotoxic quadrane natural products, which allowed the total synthesis of (1R)-suberosanone and the formal synthesis of (1R)-suberosenone. This work provides all the necessary chiroptical information for the determination of the absolute

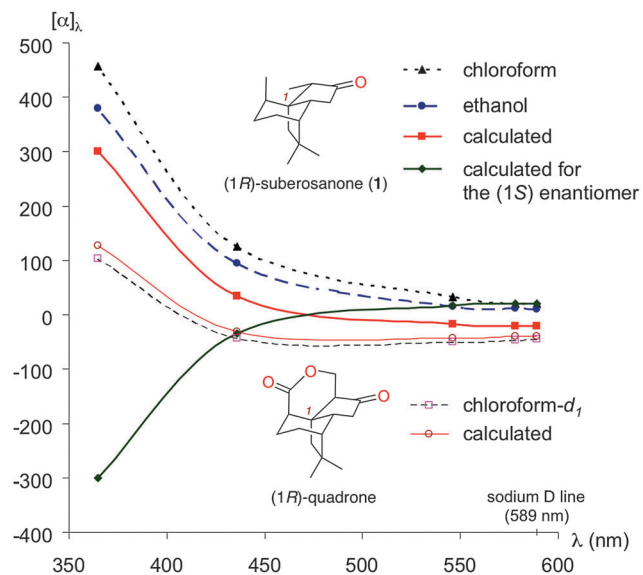

Fig. 2 Experimental and calculated ORDs of (1R)-suberosanone (**1**) and (1R)-quadrone. Data from ref. 4 and our own measurements.

configuration of naturally occurring suberosanone when more data are available.
