Photoinduced electron transfer in porous organic salt crystals impregnated with fullerenes
Photoinduced electron transfer in porous organic salt crystals impregnated with fullerenes†

Porous organic salt (POS) crystals composed of 9-(4-sulfophenyl)anthracene (SPA) and triphenylmethylamine (TPMA) were impregnated with fullerenes (C60 and C70), which were arranged in one dimensional close contact. POS crystals of SPA and TPMA without fullerenes exhibit blue fluorescence due to SPA, whereas the fluorescence was quenched in POS with fullerenes due to electron transfer from the singlet excited state of SPA to fullerenes.

As compared with MOFs, porous organic salts (POSs) have advantage in terms of synthetic versatility, easier processing, more flexibility and better workability.11–15 In particular, POSs composed of ammonium cations and sulfonate anions have enabled various systematic designs of the resultant porous structures by changing the combination of ionic components using strong intermolecular interactions such as hydrogen bonds and electrostatic interactions.16,17 However, there has been no report on photoinduced electron transfer in POS crystals.

We report herein the first example of efficient photoinduced electron transfer in POS crystals composed of 9-(4-sulfophenyl)anthracene (SPA) and triphenylmethylamine (TPMA) impregnated with fullerenes (C60 and C70) as revealed by femtosecond laser flash photolysis and electronic paramagnetic resonance (EPR) measurements. Fullerenes were chosen as electron acceptors, because they are known to undergo efficient electron-transfer reduction with small reorganization energies.18 The combination of SPA and TPMA was chosen in order to make enough space for accommodation of fullerenes in the porous structure.

SPA was synthesized according to the literature (see the ESI†).19 The organic salt composed of SPA and TPMA yielded a pale yellow needle crystal of SPA/TPMA suitable for X-ray crystallographic analysis from an o-dichlorobenzene solution. The X-ray crystal structure of SPA/TPMA in Fig. 1 revealed that the crystal had a porous structure, which was hierarchically constructed (Fig. S1 in the ESI†). Four SPA molecules and four TPMA molecules assembled into a tetrahedral supramolecular cluster via a cubic-like charge-assisted hydrogen bond.20 Anthracene moieties of SPA were jutting out in the tetrahedral direction and located around the core structure. The tetrahedral clusters accumulated along the c-axis by CH–π interactions between anthracene moieties and...
trityl groups to form a linear column structure differently from the previously formed diamondoid structures.21 The column structures were bundled by CH–π interactions between anthracene moieties to give a bowl-like void space among the columns. The void spaces were connected leading to a channel type porous structure having a bottleneck (Fig. S2 in the ESI†). Recrystallization solvents were incorporated there but disordered.

The void space of SPA/TPMA from o-dichlorobenzene with a diameter of 9.3 Å (Fig. 1) is capable of accommodating fullerenes. Recrystallization of SPA/TPMA with C₆₀ and C₇₀ gave purple-red and red-brown needle crystals, respectively. X-ray studies revealed that the porous organic salts composed of SPA and TPMA were impregnated with fullerenes as shown in Fig. 2. The crystallographic parameters of SPA/TPMA, SPA/TPMA/C₆₀ and SPA/TPMA/C₇₀ are shown in Table S1 (ESI†). The void space is enlarged by impregnation of fullerenes to be 10.8 Å and 11.1 Å in SPA/TPMA/C₆₀ and SPA/TPMA/C₇₀, respectively (Fig. S3 in the ESI†), because of comparatively weak interaction among the columns. This indicates the flexibility of the POS crystals. Moreover, the bottleneck in SPA/TPMA/C₆₀ and SPA/TPMA/C₇₀ is also expanded to be 6.6 Å and 7.2 Å, respectively. Consequently, the distance between fullerenes gets closer in the porous structures.

The SPA/TPMA crystal exhibits fluorescence due to the SPA moiety under photoirradiation (Fig. 3).22 In contrast, SPA/TPMA/C₆₀ and SPA/TPMA/C₇₀ exhibited no fluorescence probably because of electron transfer from the singlet excited state of SPA to the fullerene. The occurrence of the photoinduced electron transfer in SPA/TPMA/C₆₀ crystals was confirmed by femtosecond laser flash photolysis measurements. The observed transient absorption spectra are shown in Fig. 4, where the transient absorption band at 580 nm of SPA (1SPA*) was observed upon femtosecond laser excitation and the decay is accompanied by an increase in the new absorption band at 700 nm due to the radical cation of SPA (SPA*•).23 The concomitant formation of C₆₀•– was also observed at 1030 nm.18 Thus, photoinduced electron transfer from 1SPA* to C₆₀ occurred in SPA/TPMA/C₆₀ to produce the charge-separated (CS) state (SPA*•/TPMA/C₆₀•–).

The rate constant of photoinduced electron transfer from 1SPA* to C₆₀ was determined by the fast decay of absorbance at 600 nm due to 1SPA* to be 7.3 × 10¹¹ s⁻¹ (Fig. 5a). The decay time profile of absorbance at 700 nm due to SPA* exhibited two components as shown in Fig. 5b, where the fast component afforded a rate constant of 7.3 × 10¹¹ s⁻¹, which agrees with the rate constant of electron transfer from 1SPA* to C₆₀ and the slower component afforded a rate constant of 1.9 × 10¹⁰ s⁻¹. This value is larger than the decay rate constant of C₆₀•– (5.7 × 10⁹ s⁻¹) determined by the slower decay of absorbance at 1030 nm (Fig. 5c). The faster decay of SPA*• than the decay of C₆₀•– indicates that electron transfer from TPMA to SPA* occurred to produce the CS state (SPA*•/TPMA/C₆₀•–), which decayed with a rate constant of 5.7 × 10⁹ s⁻¹ and a CS lifetime of 180 ps. Electron transfer from TPMA to SPA* is indeed energetically feasible, because the one-electron oxidation potential of TPMA (1.20 V vs. SCE) is lower than that of SPA (1.40 V vs. SCE) as shown in their cyclic voltammograms (Fig. S5 in the ESI†).
Similarly a transient absorption spectrum of the CS state of SPA/TPMA/C60 was observed by femtosecond laser flash photolysis measurements (Fig. S6 in the ESI†). The rate constant of photoinduced electron transfer from 1SPA* to C70 was determined by the fast decay of absorbance at 600 nm due to 2SPA* to be 2.6 × 1011 s⁻¹. The CS lifetime of SPA/TPMA*⁺/C70⁻ was also determined by the slower decay of absorbance at 1030 nm due to C70⁻ to be 4.4 × 10⁵ s⁻¹, which corresponds to the lifetime of 230 ps.

Upon photoirradiation (λ > 340 nm) of single crystals of SPA/TPMA/C60 in an ESR cavity at 77 K, we could observe a signal at g = 2.0025 as shown in Fig. 6. This signal can be assigned to the superposition of TPMA*⁺ and C60⁻. In addition, we could observe a signal due to a triplet CS state, for which the zero-field splitting (D) value was determined to be 49 G. On the basis of this value, the distance between TPMA*⁺ and C60⁻ is estimated to be 8.3 Å,24 which is in good agreement with that found in the crystal structure (8.1 Å in Fig. 7).

In conclusion, porous organic salt (POS) crystals composed of 9-(4-sulfophenyl)anthracene (SPA) and triphenylmethylamine (TPMA) were successfully impregnated with fullerenes (C60 and C70) to reveal the X-ray crystal structures. Photocexcitation of POSs impregnated fullerenes resulted in efficient electron transfer from 1SPA* to fullerenes, followed by hole transfer from SPA*⁺ to TPMA to produce the final CS states (SPA/TPMA*⁺/C60⁻⁺ and SPA/TPMA*⁺/C70⁻⁺), which decayed with lifetimes of 180 and 230 ps respectively. This work has demonstrated the excellent ability of POSs impregnated with fullerenes for efficient photoinduced electron transfer. The tunability and crystalline structures of POSs impregnated with various electron acceptors provide a promising platform to develop artificial photosynthetic systems.

Notes and references

22 UV-vis and fluorescence spectra of SPA/TPMA in PhCN are shown in Fig. S4 in the ESI.

24 The distance ($r$, Å) between the two radical centres was estimated using the following equation: $r = [(2.78 \times 10^{-3})/D]^{1/3}$.
