Investigating the adsorption of peptides on inorganic surfaces, on the molecular level, is fundamental for medicinal and analytical applications. Peptides can be potent as linkers between surfaces and living cells in biochips or in implantation medicine. Here, we studied the adsorption process of the positively charged pentapeptide RTHRK, a recently identified binding sequence for surface oxidized silicon, and novel analogues thereof to negatively charged mica surfaces. Homogeneous formation of monolayers in the nano- and low micromolar peptide concentration range was observed. We propose an alternative and efficient method to both quantify binding affinity and follow adhesion behavior. This method makes use of the thermodynamic relationship between surface coverage, measured by atomic force microscopy (AFM), and the concomitant free energy of adhesion. A knowledge-based fit to the autocorrelation of the AFM images was used to correct for a biased surface coverage introduced by the finite lateral resolution of the AFM. Binding affinities and mechanisms were further explored by large scale molecular dynamics (MD) simulations. The combination of well validated MD simulations with topological data from AFM revealed a better understanding of peptide adsorption processes on the atomistic scale. We demonstrate that binding affinity is strongly determined by a peptide's ability to form salt bridges and hydrogen bonds with the surface lattice. Consequently, differences in hydrogen bond formation lead to substantial differences in binding affinity despite conservation of the peptide's overall charge. Further, MD simulations give access to relative changes in binding energy of peptide variations in comparison to a lead compound.

## Introduction

Rational modification of inorganic surfaces with peptides plays a major role for medical, pharmaceutical and technical applications. It is used for the development of biosensors<sup>1</sup> or as linkers between inorganic implants and biological tissue to increase cell viability and hence biocompatibility.<sup>2–4</sup> Protein coated mesoporous silicates were shown to promote bone regeneration.<sup>5–7</sup> These applications benefit from the largely tunable biophysical properties of peptides which enable high affinity binding to the inorganic surface material.<sup>8–10</sup>

Surface binding peptides are often discovered using combinatorial approaches like cell surface<sup>11,12</sup> or phage display methods.<sup>13,14</sup> Rational strategies however identify the binding motif of a native peptide *via* structure–activity relationship

studies with overlapping peptide sequences and aim to amplify its affinity by multiplying the identified motif.<sup>15,16</sup> Both the combinatorial and rational experimental approaches are time and material consuming and thus expensive. Furthermore, the discovery of high affinity binding peptides using these methods does not allow conclusions concerning their binding mechanism. Hence, an improvement of discrete properties of peptide coatings often remains an experimentally challenging task. The use of molecular docking or computer simulation experiments allows insights into the molecular processes during the adsorption and binding of peptides onto surfaces.<sup>17–26</sup> The challenge here is that force fields for the description of inorganic surfaces are often either not available or not compatible with the force fields that describe peptides, ions and the solvent.

In this study, the adsorption mechanism of three different peptides to an aluminosilicate was investigated using a combined approach of atomic force microscopy (AFM) and atomistic molecular dynamics (MD) simulations. The wild type peptide RTHKR (see Fig. S2, ESI†) was discovered as the peptide binding sequence for silicon oxide by rational design<sup>3</sup> from a weak binding precursor.<sup>27</sup> It is a part of the ZnO binding peptide (VRTRDDARTHRK), which was isolated in 2000.<sup>28</sup> RTHRK shows

† Electronic supplementary information (ESI) available. See DOI: 10.1039/c6cp03325c

a high affinity to metals like zinc and silica, but also to silicates like mica. In addition to RTHRK, we investigated two alternative peptide sequences, which are like RTHRK overall three fold positively charged. In the first variation, RTHRR, the highly localized charge of the amino group in lysine is exchanged with a more diffuse charge distribution of the guanidinium cation (see Fig. S2, ESI†). The second analogue, Ac-RTHRK-NH(CH<sub>3</sub>), is capped and thus has uncharged termini while restoring the overall charge of the peptide (see Fig. S2, ESI†).

Adsorption-desorption affinities of the different peptide analogues were derived from the concentration dependent adsorption as measured by AFM. *In silico* free energy calculations using umbrella sampling were applied to validate the observed adsorption-desorption behavior in atomic detail. We propose a method to predict the affinity of any peptide or protein sequence to hydrated multicomponent mineral systems and their interfaces. Our computational approach facilitates the otherwise time consuming and expensive search for suitable new peptide sequences for the various applications shown above.

## Experimental details

### Peptide synthesis

Peptides were synthesized by automated solid phase peptide synthesis (Syro I peptide synthesizer, MultiSynTech) by standard Fmoc/tBu strategy. RTHRK and RTHRR were synthesized on Wang resin (15 µmol, loading 0.6 mmol g<sup>-1</sup>). The peptide Ac-RTHRK-NH(CH<sub>3</sub>) was synthesized on ({3-[(methyl-Fmoc-amino)-methyl]-indol-1-yl}-acetyl AM resin ((15 µmol, loading 0.7 mmol g<sup>-1</sup>)). A more detailed procedure is given elsewhere.<sup>29</sup> Shortly, reactive side chains were protected with Pbf (Arg), Boc (Lys), tBu (Thr), and Trt (His). After elongation, RTHRK-NH(CH<sub>3</sub>) was N-terminally acetylated with 15 eq. acetic acid and 10 eq. *N,N*-diisopropylethylamine (DIPEA). Final cleavage of the peptides was performed with trifluoroacetic acid (TFA)/thioanisole/thiocresol (9:0.5:0.5 v/v) for 3 h shaking at room temperature. The peptides were precipitated and washed with ice-cold diethyl ether. Purification of the peptides was carried out by preparative reversed phase-high performance liquid chromatography (RP-HPLC) on a Phenomenex Jupiter Proteo column (90 Å/4 µm, 22 mm × 250 mm)) using linear gradients of Eluent B in Eluent A (A: 0.1% TFA in H<sub>2</sub>O, B: 0.08% TFA in acetonitrile (ACN)). Isolated peptides were analytically identified by matrix-assisted laser ionization time of flight mass spectrometry (MALDI-ToF-MS) (Bruker Daltonics) and electrospray ionization (ESI)-ion trap MS (Bruker Daltonics). Observed *m/z* values were in agreement with calculated molecular weights. Purity and elution properties were checked by analytical RP-HPLC with gradients of Eluent A and B. Final peptide products were obtained with a purity of ≥95% (Table 1).

### Sample preparation

The mica substrates (grade V1, Ted Pella, USA) were cut into pieces of about 1 cm × 0.5 cm and cleaved into thin slices with clean, flat surfaces on both sides. The peptides were diluted in

Table 1 Analytical data of purified peptides

| Sequence                      | <i>M</i><br>[g mol <sup>-1</sup> ] | <i>m/z</i><br>[ <i>M</i> + <i>H</i> ] <sup>+</sup> | Elution<br>[% ACN] | Purity<br>[%] |
|-------------------------------|------------------------------------|--|--------------------|---------------|
| RTHRK                         | 696.4                              | 697.4 <sup>a</sup>                                 | 7 <sup>b</sup>     | > 95          |
| RTHRR                         | 724.4                              | 725.5  | 14 <sup>b</sup>    | > 95          |
| Ac-RTHRK-NH(CH <sub>3</sub> ) | 751.4                              | 752.4  | 14 <sup>c</sup>    | > 95          |

Peptide sequences are shown by one letter code according to IUPAC. The identity of the peptides was analyzed by MALDI-ToF mass spectrometry and <sup>3</sup>ESI-ion trap mass spectrometry. The *m/z* ratio of the measured positive ions ([*M* + *H*]<sup>+</sup>) was in agreement with calculated molecular masses. The peptide purity and elution properties (hydrophilicity) were evaluated by two different RP-HPLC systems using different columns and gradients; Gradients of eluent B in eluent A on a <sup>b</sup>Phenomenex Jupiter Proteo (90 Å, 5 µm), <sup>c</sup>Phenomenex Jupiter Proteo (300 Å, 4 µm) and VariTide (200 Å, 6 µm), (not shown). Ac (acetylated), -NH(CH<sub>3</sub>) (*N*-methylated amide at the C-terminus).

TBS buffer (20 mM Tris-HCl, 150 mM NaCl, pH 7.6) to prepare several sample concentrations. The mica substrates were added to the peptide solutions in small tubes and equilibrated at room temperature for two hours. After incubation, the mica substrates were removed from the peptide solution, washed and finally rinsed with ultrapure water. The substrates were gently dried under a nitrogen stream and attached to a microscopic slide for further investigation. All samples were stored in a desiccator under reduced pressure.

### AFM measurements

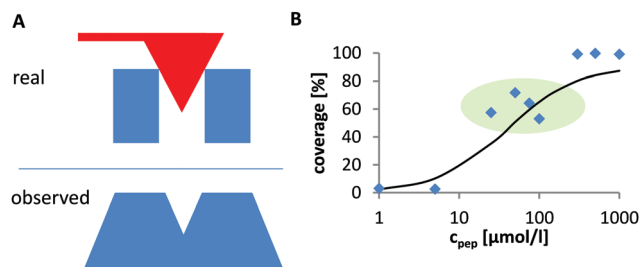

Atomic force microscopy (AFM) measurements were performed on the JPK NanoWizard II AFM system with an Olympus IX71 inverted microscope on an isolation platform. Rectangular silicon cantilevers with aluminum coating and pyramidal tips were used in intermittent contact mode (APPNANO ACTA probes, Applied NanoStructures, USA). Its nominal spring constant is 37 Nm and the nominal frequency 300 kHz. Each substrate was analyzed at least two positions with overview scans (10 × 10 µm<sup>2</sup>) and several detail scans (1 × 1 µm<sup>2</sup>) within these areas. Ambiguous samples were repeated more often to obtain reliable information about surface coverage and size and shape of peptide clusters. The samples were scanned with a resolution of 512 × 512 data points.

### AFM data analysis and processing

AFM raw data were processed by an automated line-by-line leveling using a polynomial background as implemented in Gwyddion 2.40.<sup>30</sup> Characteristic cluster shapes and sizes were extracted by analyzing the line profiles of the images.

The degree of peptide coverage of the surfaces was evaluated as a function of peptide concentration. It was necessary to identify a criterion to reliably and quantitatively differentiate between a peptide covered surface and an uncovered surface that was only incubated in pure buffer solution. The number and approximate size of the grains was analyzed using the watershed algorithm as implemented in Gwyddion (see Fig. 2B).<sup>30,31</sup> The method delivers the number of grains, their average size and the overall coverage of the surface. The results obtained for surfaces with very low degree of coverage and for fully covered surfaces were

**Fig. 1** (A) AFM image lateral broadening due to finite tip size. Two neighboring objects (blue) whose size and distance are small compared to the tip size (top). Their dimension is strongly overestimated and the two individual objects are poorly resolved. Therefore, the uncovered area between them is not detected (bottom). (B) These resolution limits lead to overestimation of the coverage, which is particularly significant for intermediate degrees of coverage where many very small and closely neighbored particles are found on the surface (marked in green).

in line with the expected behavior. In the intermediate range, the obtained concentration dependence was not satisfactory (see Fig. 1B). The reason is that these samples exhibit many small and closely neighbored peptide clusters which cannot be correctly resolved with the AFM tip (which is large compared to the aggregates and the distance between them). This led to an overestimation of the peptide coverage in the intermediate range (see Fig. 1A).

In order to overcome this problem, the average size of the detected grains was corrected by evaluating the influence of the tip shape. To this end, we first determined the 2D spatial autocorrelation function of each image and obtained the three dimensional line profile of the average grain ( $\text{Autocor}(\Delta r)$ ) (see Fig. 2C and D). Here, it is important to notice, that the autocorrelation is not time dependent. Instead, the autocorrelation is defined as the sum over all products between an image and its copy translated by the vector  $\Delta r$  in  $x$  and  $y$  direction. For a mathematical description see eqn (S1) (ESI†). This shape is determined by: (a) the true size of the underlying objects which we aim for, (b) the autocorrelation function of the AFM-tip (especially important for objects which are small compared to the tip size), (c) the autocorrelation of the noise and (d) a constant offset. Accordingly, in order to determine the average grain size, the individual contribution of every parameter was determined by fitting their linear combination to the autocorrelation profile (see eqn (1)).

$$\text{Autocor}(\Delta r) = a \cdot \text{Autocor}_{\text{objects}}(\Delta r) + b \cdot \text{Autocor}_{\text{tip}}(\Delta r) + c \cdot \text{Autocor}_{\text{noise}}(\Delta r) + d \quad (1)$$

In case of a small object (object diameter is small compared to AFM tip diameter), the shape of the object is fully hidden under the shape of the tip. The AFM image will show a circular object with the diameter of the tip  $d_{\text{tip}}$ . Its autocorrelation is therefore the autocorrelation of two circles with the diameter of the AFM tip (see Fig. 2D) as given in eqn (2).

$$\text{Autocor}_{\text{tip}}(\Delta r) = \frac{2}{\pi} \cdot \left( \arccos\left(\frac{\Delta r}{d_{\text{tip}}}\right) - \frac{\Delta r \cdot \sqrt{d_{\text{tip}}^2 - \Delta r^2}}{d_{\text{tip}}^2} \right) \quad (2)$$

Stochastic noise is a pure measurement artifact and is by definition random and independent of a neighboring measurement point (pixel). Its autocorrelation is therefore a Dirac-delta distribution (see Fig. 2D). The offset is taken into consideration by adding a constant  $d$  to the fit function (see Fig. 2D).

After all these contributions were fitted to the autocorrelation function, the only contribution left is the autocorrelation of the underlying peptide aggregates. It can be fitted as a convolution of the autocorrelations of the tip shape and a Gaussian function (for a mathematical definition see S2, ESI†). The full width at half maximum (FWHM) of this Gaussian function then gives the average diameter of the objects (see eqn (3) and (4)).

$$\text{Autocor}_{\text{objects}}(\Delta r) = (\text{Autocor}_{\text{tip}} \times \text{Autocor}_{\text{Gauss}})(\Delta r) \quad (3)$$

$$\text{Autocor}_{\text{Gauss}}(\Delta r) = \exp\left(-\frac{2 \ln(2) \Delta r^2}{\text{FWHM}^2}\right) \quad (4)$$

This corrected average grain size is not influenced by lateral broadening that arises due to the finite tip size. Knowing the number of the aggregates per image from the watershed grain analysis, it is now possible to determine the covered area as the product of the average grain size and its number. This enables a direct access to the degree of coverage and much more accurate results for the intermediate concentration range. The fit of the autocorrelation function of the images was performed using GNU Octave 3.6.4.<sup>32</sup> Commented scripts for Octave are given as ESI†.

## Molecular dynamics (MD) simulations

The simulation setup consists of a  $6.2236 \times 7.1586 \times 11.0000 \text{ nm}^3$  cubic box which is periodically multiplied in three dimensions (periodic boundary conditions). The mica layer is six Si/Al layers (labeled 'A-layer' in Fig. 3) thick and continuous in the  $x$  and  $y$  dimension. Varying numbers of overall three fold positively charged peptides (RTHRK, RTHRR or Ac-RTHRK-NH(CH<sub>3</sub>)) were added at random positions and conformations to the simulation box before the system was solvated with explicit spc water.<sup>33</sup> Finally,  $0.15 \text{ mol L}^{-1}$  NaCl was included in order to simulate physiological conditions. The system was neutralized by adding additional chloride ions. All MD simulations were run at 300 K (v-rescale coupling<sup>34</sup>) with the Gromacs 4.5.7 package.<sup>35</sup> Electrostatic interactions were calculated using the Particle Mesh Ewald method (PME),<sup>36,37</sup> with a  $1.2 \text{ \AA}$  grid and a fourth order spline interpolation. The Lennard-Jones cutoff radius was set to  $14 \text{ \AA}$ . All hydrogen bonds were constraint using the LINCS algorithm.<sup>38</sup> Peptides, water and ions were described with the Gromos 45a3 force field parameters.<sup>39</sup> The parameters for the mica surface are based on the CLAYFF force field developed by Cygan *et al.*<sup>40</sup> Cygan *et al.* describe the van-der-Waals interaction  $E_{\text{vdW}}$  between two atoms  $i$  and  $j$  which are separated by the distance  $r_{ij}$  with a Lennard-Jones-potential using the parameters  $D_0$  [ $\text{kcal mol}^{-1}$ ] and  $R_0$  [ $\text{\AA}$ ] according to eqn (5). Gromacs requires the Lennard-Jones-parameters  $C_6$  [ $[\text{kJ nm}^6] \text{ mol}^{-1}$ ] and  $C_{12}$  [ $[\text{kJ nm}^{12}] \text{ mol}^{-1}$ ]

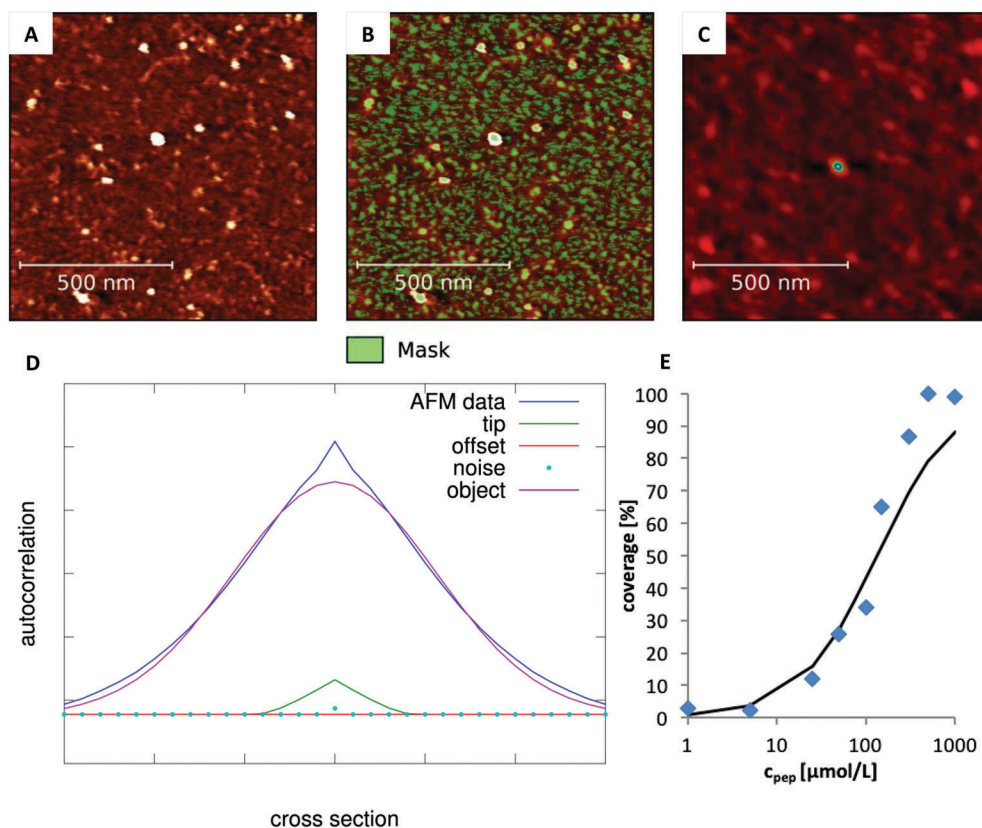

Fig. 2 Analysis of the degree of coverage. (A) Recorded AFM image with intermediate degree of coverage (Ac-RTHRK-NH(CH<sub>3</sub>), 100 μmol L<sup>-1</sup>). (B) Grains marked by watershed method. The number of grains is correct. However, their average size is overestimated due to the large tip size. (C) Autocorrelation of the image shown in A. The colored spot in the center represents the average grain size of the image (including the lateral broadening). (D) Fit of eqn (1) to the cross section of the autocorrelation function. The FWHM of the deconvoluted contribution of the underlying object (purple Gaussian function) is the diameter of the average grain object. If this is multiplied by the number of grains obtained from the watershed analysis (B), the truly covered area of image A is obtained. Analysis of all images at different concentrations then leads to the adsorption isotherm (E).

according to eqn (6). Therefore, we recalculated the parameters using eqn (7a) and (7b).

$$E_{\text{vdW}} = \sum_{i \neq j} D_{0,ij} \left[ \left( \frac{R_{0,ij}}{r_{ij}} \right)^{12} - 2 \left( \frac{R_{0,ij}}{r_{ij}} \right)^6 \right] \quad (5)$$

$$E_{\text{vdW}} = \sum_{i \neq j} \frac{C_{12,ij}}{r_{ij}^{12}} - \frac{C_{6,ij}}{r_{ij}^6} \quad (6)$$

$$C_{12} = D_0 R_0^{12} \quad (7a)$$

$$C_6 = 2D_0 R_0^6 \quad (7b)$$

The final Gromacs compatible parameters are given in Table 2. With these parameters, the interaction with peptides, ions and water can be reproduced well. As it would be computationally demanding to calculate all interactions within the mica surface correctly, the parameterization of these interactions is poor. Therefore, the positions of the mica atoms were frozen and simulations were performed within the *NVT* ensemble.

The structure of the mica surface is based on the crystal structure of muscovite mica at 25 °C.<sup>41</sup> Muscovite mica K[Si<sub>3</sub>Al<sub>1</sub>O<sub>8</sub>][Al<sub>2</sub>O<sub>2</sub>(OH)<sub>2</sub>] is a monoclinic aluminosilicate which

belongs to the group of phyllosilicates. Its most important characteristic is an almost perfect basal cleavage which is facilitated by the sheet like arrangement of the Si and Al atoms. Fig. 3 illustrates the structure of muscovite mica and its nomenclature for the MD simulation. A-type layers consist of Si/Al hexagons which are surrounded by corner connected oxygen tetrahedrons. The Si : Al-ratio in this layer is 3 : 1. Below this is a layer of Al atoms which is octahedrally surrounded by oxygen atoms. After another tetrahedrally surrounded Si/Al layer, a layer of K<sup>+</sup> ions follows. The basal cleavage of the surface is facilitated through this plane and leaves two almost perfectly plane Si/Al layers, which are used as clean and fresh substrates for AFM experiments.

Despite its complexity, we decided to use the described full atomistic model for the mica surface in order to be able to correctly simulate the hydrogen bond network between the surface and the adsorbing peptides. Simplified models for the mica structure, like a monolayer of SiO<sub>2</sub>,<sup>42,43</sup> are suitable to reproduce the negative surface charge but prevent the analysis of adsorption patterns on the atomic scale (*e.g.* the hydrogen bond network), which is needed to elucidate affinity differences between adsorbents with identical net charges. Furthermore, pure SiO<sub>2</sub> surfaces create a significant electrostatic potential,

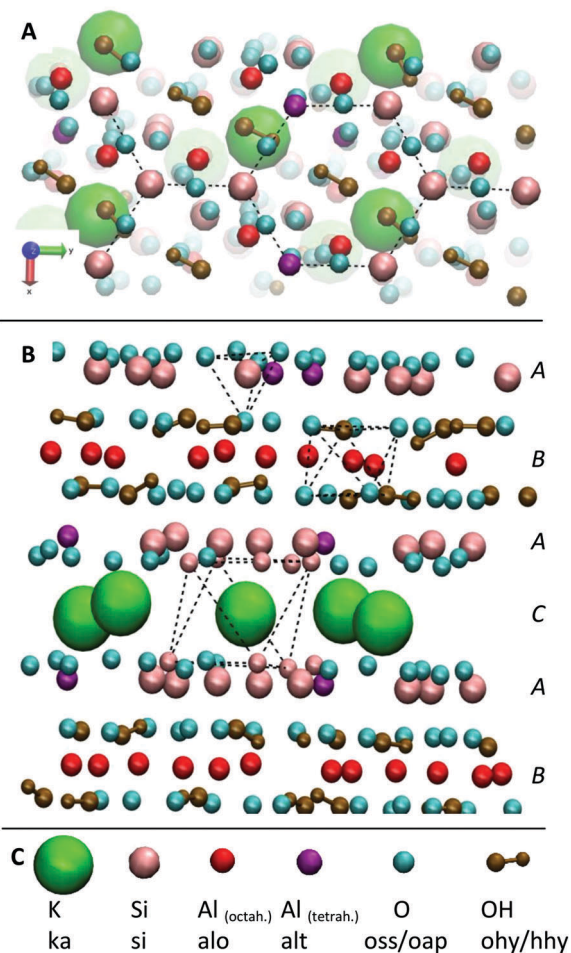

Fig. 3 Illustration of the mica surface structure. (A) View along the *c*-axis. The hexagonal structure of the Si/Al atoms in the *a*–*b* plane is highlighted. (B) View along the *a*-axis. The A–B–A–C layer structure is clearly visible: in the A-layers, silicon (pink) and aluminum (purple) are surrounded by corner-connected oxygen (cyan) tetrahedrons. In the B-plane, aluminum (red) is surrounded by edge-connected oxygen octahedrons. The C-plane consists of K<sup>+</sup> ions (green) which are surrounded by oxygen octahedrons. Cleavage along this plane leads to an extremely even surface. (C) Legend with element and MD atom names.

which is insufficiently shielded.<sup>43</sup> In real muscovite mica structures, K<sup>+</sup> cations shield the negative surface charge of the oxygen anions very efficiently (see Fig. 3 and Fig. S1, ESI†). Together with additional shielding by dissolved ions and polarization of water molecules, this leads to complete vanishing of the potential within 1.15 nm from the surface (see Fig. S1, ESI†).

The described setup was used to conduct two different types of simulations. First, increasing numbers (1, 5, 10, 15, 20, 25 and 30) of the peptide monomers (for all three peptide sequences) were added to the solution and simulated without constraints for 100 ns each. After 60 ns, a snapshot was taken to add further peptides for the next simulation run. All simulations were run for at least three repetitions to check the reproducibility of the observations. We investigated the concentration dependent adsorption mechanism and identified the main binding motifs and their driving forces.

Second, the desorption free energy was determined using the umbrella sampling algorithm and the results were compared to the adsorption free energy which was determined experimentally. To start the umbrella sampling, the adsorbed final structures of the 100 ns simulation with one peptide monomer in the solvated box were used (see above). After another equilibration of 50 ns on the surface, the peptide was desorbed by pulling it with a constant velocity from the surface in a non-equilibrium simulation run ( $k = 600 \text{ kJ (mol nm}^2)^{-1}$ ;  $v = 0.0003 \text{ nm ps}^{-1}$ ). The force that is needed for this process is larger than it would be in case of an equilibrium process, as stabilizing (solvent) relaxation processes cannot be completed during the fast process. In order to overcome this error, a series of structures from the non-equilibrium simulations was extracted and run with constrained center of mass positions to calculate the potential of mean force from the overlapping umbrella sampling windows.<sup>44,45</sup> The force constant of the position restraints for each simulation run was adapted in a way that the average center of mass position did not shift more than 0.15 nm from its input position to ensure a sufficient sampling of the complete desorption process.

For visualization of trajectories and calculation of (bond) distances and angles, the program visual molecular dynamics (VMD) 1.9.1 was used.<sup>46</sup> Other properties like temperature, electrostatic potential, electric field, Coulomb and Lennard-Jones

interaction or density were evaluated using the tools implemented in Gromacs.

### Density functional theory (DFT) calculations

To support and validate the results of the molecular dynamics simulations, density functional theory (DFT) calculations of the adsorbing functional groups of the peptides on a cutout of the mica surface were performed. Namely, we optimized the adsorption geometry of (i) a methylammonium cation (mimicking K and the N-terminus of RTHRK and RTHRR), (ii) a methylguanidinium cation (mimicking R of RTHRK, RTHRR and Ac-RTHRK-NH(CH<sub>3</sub>)) and (iii) a neutral acetyl methylamine molecule (mimicking the capped N-terminus of Ac-RTHRK-NH(CH<sub>3</sub>)) (see Fig. S2, ESI†). The mica surface was cutout in a way that one Si/Al hexagon of the *a*-*b*-plane (see Fig. S3A (ESI†) and Fig. 3A) was surrounded as realistically as possible. To this aim, we modelled additionally six adjacent Si/Al hexagons in the *a*-*b*-plane and one full repetition of the A-B-A-C layer motif in the *c*-direction (see Fig. S3B (ESI†) and Fig. 3B). In the B-layer (see Fig. 3B), the three fold positively charged Al anions are octahedrally surrounded by oxygen anions, which donate each  $-0.5e$  to the central cation. To avoid unbalanced charges at the border of the limited model, we ensured that each Al cation is surrounded by three negative charges donated by oxygen anions. To saturate left over negative charges of oxygen anions at the borders of the model, adjacent positively charged heavy atoms (Si and Al) were replaced by hydrogen atoms.

DFT calculations were carried out on the simplified model structures at the PBE0-D3/LAV2P\* level of theory as implemented in Jaguar 9.2 program (Jaguar, version 9.2, Schrodinger, Inc., New York, NY, 2016).<sup>47</sup> The PBE0-D3 density functional<sup>48–50</sup> includes physically and chemically important London dispersion interactions.<sup>51</sup> The LAV2P\* basis set uses the standard 6-31G(d) basis set for light elements and the LAV pseudopotential<sup>52</sup> for heavier elements, such as Al in this case.

## Results and discussions

The high charge density of the investigated pentapeptides leads to strong interactions with charged (or polar) surfaces like mica. The surface of muscovite mica is covered with K<sup>+</sup> ions, which are partially dissolved upon contact with aqueous solutions, leaving a negatively charged [Si<sub>3</sub>Al<sub>1</sub>O<sub>8</sub>]<sup>−</sup> surface. The high affinity of the peptide RTHRK to the mica surface led to a full coverage of the surface in the nanomolar concentration range. The same affinity was reached towards a naturally oxidized silicon surface if the peptide sequence is replicated four times ([RTHRK]<sub>4</sub>).<sup>3</sup> Hassert and coworkers showed that modification of the peptide termini with a bioactive integrin binding ligand does not reduce the affinity towards the inorganic surface, but enhances cell spreading and viability of osteoblasts on an oxidized silicon surface.<sup>3</sup>

The affinity to mica surfaces does not only depend on the overall charge of the system. Equally important are the delocalization of the charge distribution within the peptide molecule and the number of available binding sites. To investigate the

binding affinity, the degree of surface coverage was measured for mica samples incubated at different peptide concentrations. The EC<sub>50</sub> values, the concentration at which half of the surface is covered with peptide, was determined for the three different peptide sequences (see Fig. 4). The original sequence RTHRK has an EC<sub>50</sub> value of 0.41 μmol L<sup>−1</sup>. Delocalization of the charge distribution, namely the exchange of Lys with Arg (RTHRR), led to an increase of the EC<sub>50</sub> value to 98 μmol L<sup>−1</sup>. Capping of the charged termini (Ac-RTHRK-N(CH<sub>3</sub>)) displayed a similar effect and led to an EC<sub>50</sub> value of 133 μmol L<sup>−1</sup>.

Hassert *et al.* additionally measured the binding affinity of the same peptide sequence N-terminally capped with two aminohexanoic acid (Ahx) spacers and biotin (Biotin-(Ahx)<sub>2</sub>-RTHRK) to an oxidized silicon surface and determined the EC<sub>50</sub> value to be 11 μmol L<sup>−1</sup>.<sup>3</sup> In agreement to our observation, this value is significantly higher than the value for the uncapped RTHRK (EC<sub>50</sub> = 0.41 μmol L<sup>−1</sup>). It is however lower than the value for Ac-RTHRK-N(CH<sub>3</sub>). This might be due to additional polar interactions of the biotin group with the oxidized silicon surface. Hassert *et al.* determined their values by using both concentration dependent atomic force microscopy and fluorescence microscopy of a dye labelled version of the peptide and obtained very similar results.<sup>3</sup> This shows that concentration dependent atomic force microscopy is comparable to well-established fluorescence techniques,<sup>53</sup> yielding the additional advantage that topographic information of the surface coverage can be obtained.

In order to understand these results from a molecular point of view, atomistic molecular dynamics (MD) simulations were performed. An unrestrained simulation of 60 ns revealed a rapid peptide adsorption which was driven by Coulomb interactions between the negatively charged mica surface and the positively charged peptides. Each single contact between a binding site and the mica surface is reflected by a clear change within the Coulomb potential (see Fig. 5A). When the peptides were not sterically hindered by other peptides, they flatly adsorbed on the surface with all positively charged residues and the N-terminus directly bound to the surface. The interaction between the large guanidinium group of the arginine residues and the surface is relatively weak. The peptides could thus diffuse along the surface as long as no other groups are adsorbed. In contrast, the amino groups of lysine and the positively charged N-terminus bound very strongly to the surface. This interaction anchors the molecule and thus completely prevents diffusion along the surface. The strong binding is caused by close Coulomb interactions and the formation of three hydrogen bonds between the amino groups and the hexagonally arranged oxygen atoms of the mica surface (compare Fig. 5B – 20 ns, left).

To further investigate the differences of the binding motifs, additional DFT calculations of the binding of functional groups on a cutout section of the mica surface were performed. More specifically, we modelled the adsorption geometry of (i) a methylammonium cation (mimicking K and the N-terminus of RTHRK and RTHRR), (ii) a methylguanidinium cation (mimicking R of RTHRK, RTHRR and Ac-RTHRK-NH(CH<sub>3</sub>))

Fig. 4 Peptide coverage of mica surface after incubation with different peptide analogues, each at varying concentrations measured by AFM. (A) RTHRK (green box), (B) RTHRR (blue box), (C) Ac-RTHRK-N(CH<sub>3</sub>). (orange box), (D) blind sample without peptide (buffer and washing steps), (E) quantitative evaluation of the coverage degree of all three peptides at different concentrations.

and (iii) a neutral acetyl methylamine molecule (mimicking the capped N-terminus of Ac-RTHRK-NH(CH<sub>3</sub>)). Fig. 6 shows the optimized structures. It is clearly visible that the ammonium group of methylammonium binds with the highest affinity forming four well-localized hydrogen bonds to the adjacent oxygen octahedron (1.63 Å; 1.87 Å; 2.19 Å; 2.20 Å). The calculated partial Mulliken charge of the adsorbed ammonium group is +0.826 (instead of +1 in free solution). Hence, the surface oxygen anions donate  $-0.174e$  to the ammonium group. The methylguanidinium cation has a larger distance to the surface (1.97 Å; 1.99 Å; 2.22 Å) and accepts a negative partial charge of only  $-0.107e$  from the oxygen anions. Finally, the acetyl methylamine molecule, which is neutral and mimics the capped N-terminus, forms one comparatively weak hydrogen bond of 1.90 Å (receiving  $-0.052e$ ) and has therefore the lowest adsorption affinity. The observed DFT-optimized geometries and adsorption affinities of the simplified model structures thus confirm and extend the results obtained in the molecular dynamics simulations.

Apart from the differences in surface affinity, the adsorption behavior was similar for all three peptides. Initially, at low

peptide concentrations, very small peptide clusters with diameters of roughly 10–20 nm and a height of 0.3–0.8 nm were formed (see Fig. 7A and B). Considering that the tip itself has a diameter of around 10 nm, the true diameter of the peptide aggregates is in the order of 1–4 nm.<sup>54</sup> Adsorbed peptide monomers have dimensions of approximately 1.3–1.7 nm along the direction of the backbone, 1.0–1.4 nm between the outer ends of opposing side chains and a height perpendicular to the surface of 0.6–1 nm in the computational model (see Fig. 7C). Accordingly, these observed clusters must correspond to monomers and small oligomers. The number of clusters and their size grew with increasing peptide concentrations. This suggests that monomers assemble to form larger oligomeric clusters. A further increase of the concentration led to a nearly complete coverage of the mica surface with peptide. The peptide layer is extremely homogeneous and flat, except for small defect sites where no peptides were adsorbed. These defects are characterized by 0.2–0.5 nm deep holes in the AFM images (see Fig. 7D and E). Their regular size and pattern suggest that all adsorbed peptides are bound with the same binding sites and in very similar geometries. This is only possible if all adhered peptides

**Fig. 5** Adsorption of RTHRK peptides on muscovite mica. (A) Coulomb energy between peptides and mica (blue) and peptides and solvent (red) during a 60 ns simulation run. All significant changes in the profile can be attributed to specific binding events. (B) Important adsorption events that significantly change the Coulomb energy. 1 ns: peptide 1 approaches the surface and forms initial weak contact with Arg1. 2 ns: additional binding with Arg4. 20 ns: strong binding of N-terminus (right) with hydrogen bond formation between H-atoms of  $\text{NH}_3$  and oxygen anions from muscovite mica (left). 20–33 ns: further peptides adsorb. Final adsorption state is reached when Lys5 binds.

**Fig. 6** DFT optimized geometries of the peptide models (C: cyan, N: blue, O: red, H: black) adsorbing on a cutout section of the mica surface (Al and Si: grey, O: pink) and partial Mulliken charges (top) donated by the mica oxygen anions to the different peptide models. Top row: View onto the surface from above. Lower row: View along the surface from the side. (A) Methylammonium cation (mimicking K and the N-terminus of RTHRK and RTHRR), (B) methylguanidinium cation (mimicking R of RTHRK, RTHRR and Ac-RTHRK- $\text{NH}(\text{CH}_3)$ ) and (C) neutral acetyl methylamine molecule (mimicking the capped N-terminus of Ac-RTHRK- $\text{NH}(\text{CH}_3)$ ).

are in contact with the surface. This implies that a monolayer was formed which is further supported by the dimensions of the holes (see Fig. 7E and F). Molecular dynamics (MD) simulations validated these assumptions. At low peptide concentrations,

oligomers were not formed in solution. Interactions between non-adsorbed peptides and adsorbed peptides remained possible. These interactions were, however, relatively weak and reversible. The dominating peptide–surface interactions typically led to a

**Fig. 7** Peptide adsorption at different concentrations measured by AFM (left). Several line profiles were extracted to demonstrate the typical structure of the different samples (middle). Their dimensions are compared to structures obtained from MD simulations (right) (A–C) at low peptide concentrations, only isolated small aggregates with dimensions of 10–20 nm (1–4 nm after correction for finite tip size) were observed (A and B). These clusters are mainly composed of single peptide monomers (C). (D–F) At intermediate peptide concentrations, a very flat and homogeneous surface with holes was formed (D). The depth of the holes at defect sites (E and F) suggests that a monolayer of peptides is formed. (G–I) At higher concentrations, spherical superstructures on top of the monolayer were observed (G and H). The reason for the cluster formation is the hydrophobic effect which led to an exposure of the positively charged binding sites to the solution (I).

dissociation of the peptide oligomers at low concentrations. This behavior changed when the monolayer was complete and the concentration was further increased. At very high peptide concentrations, oligomer formation in solution became more likely. The hydrophobic effect led to an assembly of the hydrophobic parts of the peptides in the inner part of the oligomers, while the charged groups were exposed to the solvent. These oligomers can readily adsorb to the surface and form clusters (compare Fig. 7I). This mechanism explains the cluster formation observed in the AFM experiments at higher concentrations (compare Fig. 7G and H).

Next, it was checked if the simulations can reproduce the observed differences in the affinity to mica surfaces of the three peptides. To this aim, the desorption free energy of all three variants was determined using the umbrella sampling technique (see Fig. 8).

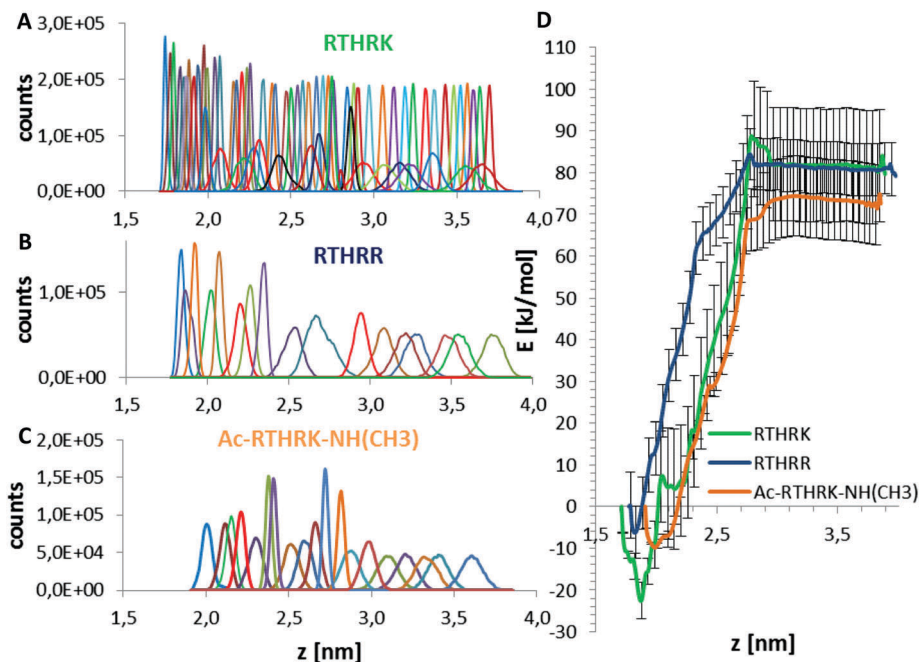

The desorption free energy, which is defined as the difference between the equilibrium value in the desorbed state and the potential minimum in the adsorbed state (see Fig. 8D), indeed correlates to the observed adsorption behavior. The original

sequence RTHRK shows the highest affinity in the adsorption isotherm measurements and has the largest desorption free energy ( $\Delta_R G \approx 100 \text{ kJ mol}^{-1}$ ). An exchange of lysine with arginine (RTHRR) led to a decrease of the desorption free energy of around  $20 \text{ kJ mol}^{-1}$ . On the same order of magnitude, although slightly smaller, is the desorption free energy of the end group capped analogue Ac-RTHRK-NH(CH<sub>3</sub>).

To directly compare desorption free energies  $\Delta_R G$  of the experiments and the simulations, the equilibrium constants  $K$  of the adsorption–desorption reactions were calculated. To fit the experimental data, the classical Langmuir model as given in eqn (9) was applied. The inherent approximations of this simple model (homogeneous and uniform surface; negligible interactions between immobilized, adsorbed peptides; monolayer coverage only) are well fulfilled for the investigated concentration range. The equilibrium constant  $K$  is presented as dimensionless quantity in eqn (8).

$$\Delta_R G = -RT \ln K \quad (8)$$

**Fig. 8** Free energy calculation of the desorption of peptides from the mica surface using umbrella sampling and the bootstrapping algorithm. (A–C) Umbrella histograms for the desorption of RTHRK (A), RTHRR (B) and Ac-RTHRK-N(CH<sub>3</sub>) (C). (D) Average desorption free energy and standard deviation from bootstrapping compared for the three peptides. Note that the desorption process started from a peptide conformation which is restrained to a shorter peptide–surface distance than the equilibrium conformation in the adsorbed state. Hence, initial elongation of the peptide–surface distance leads to a reduction of the free energy until the equilibrium adsorbed state is reached. Now, the energy increases until the attractive forces between the peptide and the surface become negligible and the fully desorbed and dissolved equilibrium state is reached.

Here,  $R$  is the ideal gas constant, while  $T$  describes the temperature.

A fit of the data (surface coverage  $\theta$  depending on the peptide concentration in solution  $c_{\text{Pep}}$ ) to the Langmuir model delivers the equilibrium constant with the unit [L mol<sup>-1</sup>].

$$\theta = \frac{Kc_{\text{Pep}}}{1 + Kc_{\text{Pep}}} \quad (9)$$

In order to obtain a dimensionless quantity that can be used for eqn (8), we calculate the equilibrium constant for reaction (R1).

In reaction (R1),  $\text{Pep}_{(\text{aq})}$  is the concentration of dissolved peptides,  $\text{Pep}_{(\text{ads})}$  describes the concentration of adsorbed peptides,  $*_{(\text{ads})}$  denotes the concentration of free binding sites at the surface and  $*_{(\text{aq})}$  stands for the remaining possible peptide concentration in solution before the saturation limit is reached.

The equilibrium constant  $K$  and the coverage degree  $\theta_{\text{ads}}$  for reaction (R1) are defined in eqn (10) and (11).

$$K = \frac{[\text{Pep}_{(\text{ads})}][*_{(\text{aq})}]}{[\text{Pep}_{(\text{aq})}][*_{(\text{ads})}]} \quad (10)$$

$$\theta_{\text{ads}} = \frac{[\text{Pep}_{(\text{ads})}]}{[\text{Pep}_{(\text{ads})}] + [*_{(\text{ads})}]} \quad (11)$$

Eqn (11) was reformulated as shown in eqn (12).

$$\frac{\theta_{\text{ads}}}{1 - \theta_{\text{ads}}} = \frac{[\text{Pep}_{(\text{ads})}]}{[*_{(\text{ads})}]} \quad (12)$$

Eqn (12) was used to simplify the expression for the equilibrium constant in eqn (10) (see eqn (13)).

$$K = \frac{\theta_{\text{ads}}}{1 - \theta_{\text{ads}}} \frac{[*_{(\text{aq})}]}{[\text{Pep}_{(\text{aq})}]} \quad (13)$$

Considering the enormous access of free peptide solution compared to the small number of binding sites on the limited mica surface, it is reasonable to approximate  $[\text{Pep}_{(\text{aq})}]$  with the input concentration of the peptides:  $[\text{Pep}_{(\text{aq})}] \approx [\text{Pep}]$ . It can be assumed that  $*_{(\text{aq})}$  is equal to the space filled with water in the sample  $V(*_{(\text{aq})}) \approx V(\text{H}_2\text{O})$ . Finally, considering the similar densities of peptide and water the ratio  $[\text{Pep}]/[\text{H}_2\text{O}]$  can be approximated by the mass fraction  $w_{\text{Pep}}$ . Accordingly, eqn (13) can be simplified as given in eqn (14).

$$K = \frac{\theta_{\text{ads}}}{1 - \theta_{\text{ads}}} \frac{1}{w_{\text{Pep}}} \quad (14)$$

The mass fraction  $w_{\text{Pep}_{1/2}}$  at  $\theta_{\text{ads}} = 0.5$  was determined in the concentration dependent coverage investigations with AFM and simplifies eqn (14) to eqn (15).

$$K = \frac{1}{w_{\text{Pep}_{1/2}}} \quad (15)$$

**Table 3** Comparison of free energies of peptide adsorption on mica surface estimated using umbrella sampling (MD) and determined by concentration dependent adsorption isotherms (exp.)

|                               | $\Delta_{\text{R}}G_{\text{ads}}$ (MD) [kJ mol <sup>-1</sup> ] | $\Delta_{\text{R}}G_{\text{ads}}$ (exp.) [kJ mol <sup>-1</sup> ] |
|-------------------------------|--|--|
| RTHRK                         | -103 ± 21  | -37 ± 2  |
| RTHRR                         | -84 ± 25   | -24 ± 2  |
| Ac-RTHRK-NH(CH <sub>3</sub> ) | -78 ± 20   | -23 ± 3  |

The equilibrium ratio in eqn (15) is dimensionless and was used to calculate the desorption free energies (see eqn (8)) as given in eqn (16). Table 3 summarizes the free energies of peptide adsorption.

$$\Delta_{\text{R}}G = RT \ln w_{\text{Pep}/2} \quad (16)$$

The relative trend in surface affinity was correctly predicted by the computer simulations but the absolute adsorption free energies were overestimated. This overestimation of free energies was mainly caused by differing conditions in the experimental and computational setup. A single adsorption/desorption event of an isolated peptide on a bare mica surface was studied in the simulations. Accordingly, the investigated peptide monomer experienced the full negative charge of the mica surface. In contrast, for the calculation of the experimental desorption free energy, the concentration at half coverage was used. If half of the negatively charged surface is covered with three fold positively charged peptides, the negative surface charge is partially shielded and the average attractive Coulomb forces between the peptides and the surface decrease. Therefore, the experimentally determined adsorption free energy is likely smaller. Further reasons like force-field inaccuracies and non-equilibrium effects (e.g. seeding effects due to strong and highly localized Coulomb interactions and hydrogen bonds) may additionally explain such a systematic overestimation. Nevertheless, it was possible to correctly predict the relative affinity of the analogues in comparison with the wild type peptide using umbrella sampling.

## Summary and conclusion

In this work, we investigated the adsorption behavior of the pentapeptide RTHRK and two analogues of it on a mica surface using a combined approach of atomic force microscopy (AFM) and atomistic molecular dynamics (MD) simulations. We experimentally quantified the binding free energy by evaluating the concentration dependent coverage of the surfaces. To correct for a bias introduced by the limited AFM lateral resolution, a novel knowledge-based autocorrelation function was used. In combination with the atomistic simulations, this approach allowed us to quantify the binding affinity and describe the binding mechanism in detail over a large range of peptide concentrations and coverage. All three peptide variations formed homogeneous monolayers. In addition, we identified the main driving force and correctly predicted the differences in the adsorption behavior of the three peptide sequences. Although the adsorption process is driven by Coulomb interactions and the net charge of all investigated

peptides is equal, the differences in hydrogen bond formation led to significant differences in the binding affinity.

The presented approach is a valuable tool which enables the identification and design of novel silicate binding peptides. Computer simulations will save time and cost and allow a systematic investigation of peptide groups. The simulations also facilitate a more detailed understanding of the interaction motifs of already known high-affinity peptides and their optimization.
